Proceedings of the 19th International Conference on

Flexible Automation and
Intelligent Manufacturing

FAIM 2009

July 6th – July 8th, 2009
Teesside University, Middlesbrough, UK

Editor: Farhad Nabhani
Co-editors: Catherine Frost
           Sara Zarei
           Munir Ahmad
           William. G. Sullivan
PREFACE

The 19th International Conference on Flexible Automation and Intelligent Manufacturing (FAIM), has a rich and time-tested tradition of excellence culminating in the FAIM2009 conference at Teesside University in Middlesbrough, England. The 1st International FAIM conference in 1991 resulted from collaboration between the University in Limerick (UL) and the Virginia Polytechnic Institute. Prof. Munir Ahmad (then UL), and Prof. Bill Sullivan (then Virginia Tech.) have been central to the development of the Conference since its inception. Since 1991 FAIM has been hosted in many prestigious Universities on both sides of the Atlantic:

1991 University of Limerick, Limerick, Ireland
1992 Virginia Tech (in Washington DC), USA
1993 University of Limerick, Limerick, Ireland
1994 Virginia Tech, Blacksburg, Virginia, USA
1995 University of Stuttgart, Germany
1996 Georgia Institute of Technology, Atlanta, USA
1997 University of Teesside, Middlesbrough, UK
1998 Portland State University, Portland, Oregon, USA
1999 Tilburg University, Tilburg, Netherlands
2000 University of Maryland, Maryland, USA
2001 Dublin City University, Dublin, Ireland
2002 Dresden University of Technology, Dresden, Germany
2003 University of South Florida, Tampa, USA
2004 Ryerson University, Toronto, Canada
2005 University of Duesto, Bilbao, Spain
2006 University of Limerick, Limerick, Ireland
2007 Penn State Great Valley, Philadelphia, USA
2008 University of Skövde, Sweden

This year, the FAIM conference is organized by the Teesside University, Middlesbrough. Papers were accepted from authors from 37 countries. All accepted 192 papers for this year’s conference proceedings were rigorously peer reviewed and carefully selected from more than 275 abstracts submitted to the Conference.

The topics covered in the papers include:

- Bio-Engineering
- Business Process Re-Engineering
- Business Process Re-Engineering, Lean and Agile Manufacture
- CAD/CAM Flexible Manufacturing, CIM
- Change Management
- E-manufacturing
- Engineering for Sustainability
- Environmental Engineering
- Global Manufacturing
The FAIM 2009 conference focuses on “lean manufacturing and services” covering current research, best practices and future trends within the areas of global competitiveness and rapidly advancing technologies in flexible automation, information management, and intelligent manufacturing. FAIM 2009 provides a forum for both researchers and practitioners in the field of Flexible Automation and Intelligent Manufacturing to share the latest research, developments, and practices in the areas of the conference scope. Papers included in the proceedings address applications of these technologies and methods to the manufacturing environment, from industrial and academic perspectives.

Manufacturing today must adjust to dynamic markets which demand excellence in areas of cost, quality, throughput, innovativeness, and time to market. Manufacturing companies must master emerging and rapidly advancing technologies in order to remain competitive. They are challenged to achieve short product development cycles, expand product lines, and combat shrinking product life cycles in a global economy marked by rapid fluctuations and increasing competitions. This tradition will be continued next year in San Francisco, USA where they will host the next FAIM conference.
ACKNOWLEDGEMENTS

As the chairperson of the 19th International Conference on Flexible Automation and Intelligent Manufacturing (FAIM2009), I am indebted to many individuals for their contribution, support, and endorsement. I wish to thank all keynote speakers who shared their views and visions towards flexible automation and intelligent manufacturing. I also wish to acknowledge, with many thanks, the contributions of all authors who presented their work at the conference and submitted quality papers for this proceedings publication. My special thanks are extended to all FAIM 2009 peer reviewers and session moderators who helped ensure the high quality of the conference.

I would further like to acknowledge the contribution of the International Program and Local FAIM Organizing Committees, for their work in scheduling, the preparation of the papers, session moderation, organization of the social events, and the general operation involved in running this international conference. I would like to thank Caterpillar Ltd and Cummins Engine UK for hosting the FAIM industrial study visit.

The continued success of FAIM can be attributed to the guidance of its two founders, Prof. M. M. Ahmad and Prof. W. G. Sullivan, whom I would like to acknowledge and thank. I would also like to thank many former organisers of FAIM for their heart warming advice and support.

I would like to acknowledge the role of Teesside University and wish to express my sincere thanks to Professor Graham Henderson, the Vice Chancellor and Professor Simon Hodgson, Dean of School of Science and Technology for support in running such a prestigious conference, and thank you to all the support staff who often go unnoticed.

Although there are many who deserve credit for their various contributions to the success of FAIM 2009, there is someone who deserves special recognition and big thanks for her outstanding efforts, tireless work and commitment, Ms. Catherine Frost the Conference Organizer. Without her hard work, this conference and its proceedings would have been impossible.

Also I wish to acknowledge the excellent editorial team Sara Zarei, Martin McKie and Dr Thanos Klonis for their work as the local internal conference support team; their patience and enthusiasm for this editing this work are sincerely appreciated.

Professor Farhad Nabhani
Chair of FAIM 2009 Conference
FAIM 2009 TEAM AND COMMITTEES

CHAIR

- Prof Farhad Nabhani, University of Teesside, UK

CO-CHAIRS

- Prof. Munir Ahmad, University of Teesside, Middlesbrough, U.K
- Prof. Zulf Ali, University of Teesside, Middlesbrough, U.K
- Prof Simon Hodgson, University of Teesside, Middlesbrough, UK
- Prof. Bill Sullivan, Virginia Polytechnic Institute and State University, U.S.A.

ORGANISATION COMMITTEE

- Elaine Bradwell
- Simon Hodgson
- Jayne Laverick
- Paul McGrath
- Farhad Nabhani
- Mark White
- Amanda Wright

SCIENTIFIC COMMITTEE

- Esther Alvarez, Universidad de Deusto, Bilbao, Spain
- Jalal Ashayeri, Tilburg University, The Netherlands
- Farid Benyahia, College of Engineering, Qatar University
- Shahroz Connolly, University of Teesside, UK
- Marjan Darabi, Damyaran Arak Ltd, Iran
- Leo J De Vin, University of Skovde, Sweden
- S M T Fatemi Ghomi, Amirkabir University of Technology, Iran
- Farnaz Ganjeizadeh, California State University, USA
- Bill Gaughran, University of Limerick, Ireland
- Mark Gerrard, University of Teesside, UK
- Sunderesh S Heragu, University of Louisville, USA
- George Q Huang, University of Hong Kong, HK
- Winifred Ijomah, University of Strathclyde, UK
- Riham Khalil, De Montfort University, UK
- Ravi Y Kumar, National Institute of Technology, Warangal, India
- Feng Lin, Tsinghua, P.R.China
- Richard Lindeke, University of Minnesota Duluth, USA
- Gonzales Mejia, University De Los Andes, Colombia
- Norhamidi Muhamad, University of Kebangasaan, Malaysia
- Stephen T. Newman, Bath University, UK
• Chike F Oduoza, University of Wolverhampton, UK
• David L Olson, University of Nebraska, USA
• C S P Rao, National Institute of Technology, Warangal, India
• Olli-Pekka Hilmola, Lappeenranta University of Technology, Finland
• David Russell, Penn State Great Valley, Philadelphia, USA
• Michael A Saliba, University of Malta, Malta
• Ignacio Eguia Salinas, Universidad de Sevilla, Spain
• Thomson Sarkodie-Gyan, University of Texas, El Paso, USA
• Mohammed Sarwar, Northumbria University, UK
• Paul Shelton, University of Teesside, UK
• Piotr Skawinski, Warsaw University of Technology, Poland
• Dusan Sormaz, Ohio University, USA
• Janis P Terpenny, Virginia Tech, USA
• Uday Venkatadri, Dalhousie University, Canada
• Lihui Wang, National Research Council, Canada
• Gerald Weigert, Technische Universitat Dresden, Germany
• David A Wyrick, Texas Tech University, USA

EDITORIAL COMMITTEE

• Athanosis Klonis
• Martin Mckie
• Sara Zarei

CONFERENCE SECRETARY

• Catherine Frost
# Table of Contents

## Keynote Lecturers

**Engineering for Sustainability**  
Graham Hillier ................................................................. 1

**Successful Continuous Improvement – How to make and sustain improvements**  
Keith Copeland ............................................................. 2

**RFID-Enabled Wireless Manufacturing Execution Platform**  
George Q. Huang .......................................................... 3

**Process Industry in the UK and in a regional context**  
Stan Higgins ................................................................. 4

**Where lies the Factory of the Future?**  
David W Russell ............................................................. 5

## Bio. Engineering

**Framework of Grinding Process Modeling and Simulation Based on Microscopic Interaction Analysis**  
Xuekun Li, Yiming Rong .................................................. 6

**Clean Technology approach for use of micro-bioreactor in Bioprocess Engineering**  
Pattanathu K.S.M. Rahman, Godfrey Pasirayi, Vincent Auger, and Zulf Ali .................. 14

**Contact Area, Pressure Distribution, and Mechanical Stability in External Arthrodesis of the Ankle Joint**  
C.J. Connor, F. Nabhani and S. Hodgson ........................... 23

**Bracing Shoulder Injuries caused by Rear impacts.**  
D J Hughes, F Nabhani and S Hodgson ............................... 29

## Business Process Re-Engineering

**Inventory System Improvement in ERP Implementation Projects**  
Michael Boyce, Dr. Nasreddin Dhafr & Robert Lee ..................... 37

**Embedding ERP in an Engineering Projects Environment**  
Robert Lee, Michael Boyce, Ahmed Abbas and Nasreddin Dhafr ................. 45

**Design of a Generic Methodology Framework for Process Diagnostics Management**  
Jiri Tupa and Chike Oduoza .............................................. 52

**Global Manufacturing: Creating the Balance between Local and Global Markets**  
Parisa Gilani and Yasamin Razeghi .................................... 60
Potential of Benchmarking
Munir Ahmad ............................................................................................................................. 67

**BUSINESS PROCESS RE-ENGINEERING, LEAN & AGILE MANUFACTURE**

Moving towards Creating an Organic Lean Manufacturing Organisation
Sadri Gilani and Yasamin Razeghi ............................................................................................................. 75

The strategic importance of ERP screening process: Evidence from the forging industry
Athanosis Klonis and Ruben Pinedo-Cuenca ......................................................................................... 81

Simultaneous QFD-Based Optimization of Manufacturing System for Multiproduct Operation
George M. Bacioiu and Zbigniew J. Pasek .......................................................................................... 89

**CAD/CAM FLEXIBLE MANUFACTURING, CIM**

CAD of Main Spindle and Feed Drives for CNC Machine Tools
Zoran Pandilov and Vladimir Dukovski .................................................................................................. 97

Interaction of natural inspired methods in process planning
Cornelia Teich, Daniel Kretz, Matthias Richter, Joerg Militzer and Tim Neumann ............................ 105

Computerized System for Progressive Die Layout Design
Mohamad Ali Farsi and B. Arezoo .......................................................................................................... 112

Implementation of a Modular Supervision System for a Flexible Manufacturing Cell
Joao C.E. Ferreira, Hugo G. Santos, Marcelo T. dos Santos and Léo Schirmer ................................. 122

Cooperative robot kinematics to perform load sharing tasks
Cristiane P. Tonetto and Altamir Dias ................................................................................................. 130

On parametric toolpath design of a robot serving a press-brake
Nikolaos Kontolatis, George-Christopher Vosniakos and Konstantinos Kyriakopoulos .................... 139

The Digital Factory Concept from Manufacturing to Services Environment
Fabio Fruggiero and Alfredo Lambiase ............................................................................................... 147

Object techniques in an integration of technical and organizational production preparation processes
Cezary Grabowik ........................................................................................................................................ 155

A STEP-NC Process Planning System for CNC Turning Operations
X. Zhang, R. Liu, A. Nassehi and S. T. Newman ................................................................................ 163

Mathematical model of 6-axis CNC spiral bevel and hypoid milling machine
Piotr Skawinski ........................................................................................................................................ 171
CHANGE MANAGEMENT

Corporate Social Responsibility – a new trend in company management
Marcela Srchová, Lilia Dvořáková and Tereza Kadlecová ...................................................... 179

E-MANUFACTURING

Web-DPP: A Distributed Process Planning System for Adaptive Machining Operations
Lihui Wang, Ji Ma and Hsi-Yung Feng ................................................................. 186

Implementation of Automobile Spare Tire Inserting System using Augmented Reality
Hong-Seok Park, Jin-Woo Park and Hung-Won Choi ................................................................. 194

Design of Collaborative BOM Management System for Small and Medium Enterprises
Bo Hyun Kim, So Young Jung, Jae Yong Baek, Seok Woo Lee, and Hun Zong Choi .......... 202

ENGINEERING FOR SUSTAINABILITY

Active Disassembly application to enhance Design-for-Remanufacturing
J D Chiodo and W L Ijomah ................................................................................... 210

The Fault-Ride-Through Capacity of Doubly-Fed Induction Generators (DFIGs) for Wind Applications
Wenping Cao and Jessada Stevenson ........................................................................ 218

Predictive Simulation for Model Based Energy Consumption Optimisation in Manufacturing System and Machine Control
Anton Dietmair, Alexander Verl, and Philipp Eberspaecher ................................................... 226

Bionics – An Inspiration for Intelligent Manufacturing and Engineering
Bill Gaughran and Sonya Quinn ...................................................................................... 234

Environmental Management Systems in Smaller Enterprises (Problems and Solutions)
Mike Gallagher, William Gaughran and Pat Phealan ......................................................... 242

ENVIRONMENTAL ENGINEERING

Using biofiltration to clean waste gases
A M Gerrard, J Skalicky and J Paca .............................................................................. 250

Voluntary Environmental Instruments - their benefits and usage in the Czech Republic
Tereza Kadlecová (nee Fidlerová), Lilia Dvořáková and Marcela Srchová ......................... 257

GLOBAL MANUFACTURING

Manufacturing of a Pick-and-Place Robot with Inverse Dynamic and Robust Controllers
S. Saeed Mirian, S. Mohsen Safavi ................................................................. 265
HEALTH AND SAFETY

A Survey on Impacts of Shift Work to Shop Floor Workers’ Safety and Health in a Manufacturing Company
Baba Md Deros, Nor Kamaliana Khamis, Ahmad Rasdan Ismail, and Asri Ludin ................274

Health and safety perspective on medical waste management in a developing country: A case study of Dhaka city
M. A. Patwary, W. T. O’Hare, G. Street, K. M. Elahi, S. S. Hossain and M. H. Sarker ..........282

High Efficiency Cloning of Drug Resistance Genes Via Safe Vector Host Systems
Connolly S.S. and Connolly S.N. ............................................................................................ 291

HUMAN FACTORS AND HUMAN RESOURCES IN MANUFACTURING

Introducing a lean recruitment framework for manufacturing
Paul M Gibbons ..........................................................295

The Demographic Change in Firms of Western Industry Nations - Managerial Implications for Working Systems Design
Marion A, Weissenberger-Eibl and Johann Schwenk ................................................303

Analysis of the Methods Time Measurement (MTM) Methodology through its Application in Manufacturing Companies
Denis L. M. de Almeida and João C. E. Ferreira .................................................................311

A Neural Network Approach for Measuring the Impact of Knowledge Management on Organizational Performance of Turkish SMEs
Ali Turkyilmaz, Erkan Bayraktar, Halil Zaim and Selim Zaim .......................................319

INDUSTRIAL AUTOMATION AND PROCESS CONTROL

A Metric for Rating the Effectiveness of Installed Industrial Automation Systems using an Adjusted Function Point Analysis
David W. Russell .................................................................................................................... 328

CAN Protocol in diffuse controlling system based on B&R hardware
J. Swider, G. Kost, G. Wszelek and D. Reclik ...............................................................336

Fruit Color and Shape Grading Using a New Vision System
H. Golnabi, R. Jafari, A. Haghighatzadeh and E. Jali .........................................................343

Feasibility of an AIDC System within a Manufacturing SME
Sara Zarei, Simon Hodgson and Farhad Nabhani .............................................................351

Design of a Cobot with Three Omni-Wheels
Z. M. Bi and Lihui Wang ........................................................................................................360
Surface Monitoring by Color Reflectance Measurements
H. Golnabi, A. Haghighehtadeh and S. Dabagh ................................................................. 368

Semi-Open Queuing Network Approach for Modeling Autonomous Vehicle Storage and
Retrieval System
Banu Y. Ekren, Sunderesh S. Heragu, Ananth Krishnamurthy and Charles J. Malmborg ...... 376

A Method for the Calibration of a 3-D Laser Scanner
Cesare Rossi, Vincenzo Niola, Sergio Savino and Salvatore Strano .............................. 383

A New Real Time Shape Acquisition with a Laser Scanner: First Test Results
Cesare Rossi, Vincenzo Niola, Sergio Savino and Salvatore Strano .............................. 391

Development of a Modular, Reconfigurable End Effector for the Plastics Industry: A Case
Study

ABSTRACT:

There have always been three main principles behind successful business. They are:

- Economic factors – that create the wealth to do things and continue to do them
- Environmental, or natural resource factors – the impact we have on the resources available to us on the Earth
- And Societal factors – that people have healthy, happy and full lives.

The world is facing ever-increasing pressures on its natural resources. Population in 2003 was 6 billion and the UN forecasts that there will be over 8 billion people by 2030. All of these people need homes and services and many aspire to a developed world standard of living. In addition to the rapid growth in population and basic need, energy prices are rising and security of supply is becoming a major issue. There is also an increasing belief that humans are causing severe damage to the global environment.

Creating a balance between the economic, environmental and societal factors is what is now termed sustainable development. The modern engineer has a key role in helping the global community respond by developing and introducing technologies that deliver a more balanced approach.

This paper looks at how the engineer’s role will change to respond to these needs by taking a new look at problems and processes. It discusses how engineering technology can help make better use of the planet’s natural resources by using novel engineering systems and processes. It also considers the interaction between engineering, the built environment and social impacts.

Successful Continuous Improvement – How to make and sustain improvements

Keith Copeland MBE

Senior Engineer NMW and V-UP Office
Nissan Motor Manufacturing (UK) Limited
Sunderland Plant

ABSTRACT
As the global economy continues to free fall at a staggering rate manufacturers are facing ever increasing pressures not just to remain competitive but to survive. Realising the urgent need for increased productivity whilst reducing costs, many have been forced to adopt numerous Improvement Methodologies. Research has found that 72% of these methodologies are failing to deliver expected improvements with companies failing to align improvement strategies with their actual business needs; whilst other issues included a failure to sustain improvements beyond a 12 month period.

This session will discuss the processes used by Nissan in their approach to continuous improvement and how they have coped with the current market difficulties they face. The session will also discuss research from the Nissan supplier base and wider manufacturing sectors looking at the reasons for failure and poor sustainability looking at how companies identify issues within their organisations and how they select the appropriate tools or methodologies to address these issues.
RFID-Enabled Wireless Manufacturing Execution Platform

Professor George Q. Huang

Department of Industrial and Manufacturing Systems Engineering,
The University of Hong Kong,
Pokfulam Road, Hong Kong, P. R. China

ABSTRACT

This talk discusses how RFID (Radio Frequency Identification) technology is used to develop real-time and easy to use information platform for reconfigurable manufacturing enterprises. RFID devices are deployed at the shop-floor for collecting real-time manufacturing data from manufacturing facilities, cells and lines. The platform interacts and interoperates seamlessly with enterprise information systems such as ERP (Enterprise Resource Planning) and WMS (Warehouse Management Systems). The adoption of the platform improves productivity and product quality while reducing costs and reworks through real-time information traceability and visibility. The enterprise competitiveness is ultimately improved through better market and engineering responsiveness. The talk is divided into three parts. The first part is mainly concerned with how RFID devices are deployed to value-adding manufacturing objects and facilities such as machine tools, pallets, materials, tools, operators and Work In Progress (WIP) items. The second part of the talk will deal with how smart objects are combined with production processes and operations in order to achieve the seamless integration between shop-floor and enterprise information systems. Finally, visibility and traceability facilities are presented for different types of users such as shop-floor supervisors, process planners, production planner and schedulers, equipment maintenance engineers, and line operators. These facilities will allow them to visualize and monitor the status and provide real-time decision supports.

Where lies the Factory of the Future?

David W Russell, PhD FBCS, FIET, FI MechE

Penn State Great Valley
Malvern, PA 19355, USA

ABSTRACT:
The Factory of the Future will regretfully evolve slowly as the number of new manufacturing facilities declines in the Western hemisphere and increases in Asia. The call for sustainability often falls on ears defeaned by short term commercial advantage. Undeveloped and developing nations are striving to reach a par with the so-called developed nations – largely in the west – at whose door, along with power stations, much of the environmental problems can be laid.

The emergence of the Knowledge Economy has brought about the reality of worldwide access to information and potential markets; ubiquitous computing will ensure that future generations will be as totally blasé and dependent on IT as previous ones were on printers and FAX machines! What is changing at an incredibly rapid pace is the universal level of dependency on convenience, service, and automation that is based on information technology.

As world societies adopt the consumerism and service-centric lifestyle so prevalent in the west, there will continue to be a need for low cost, high quality and hopefully eco-friendly, technocentric products, but how and where will they be manufactured?

This paper attempts looks at some existing, and future, technologies that seem to be very promising in assisting in the manufacture of better products, more efficiently while solving many of the challenges that corporations must face in implementing them, and looks at the possibilities of the next 20 years and beyond.

Framework of Grinding Process Modeling and Simulation Based on Microscopic Interaction Analysis

Xuekun Li*, Yiming Rong

Computer-Aided-Manufacturing Lab, Manufacturing Engineering Program
Worcester Polytechnic Institute
Worcester, MA, 01609, US

ABSTRACT:

This paper describes a framework of grinding process modeling to understand grinding fundamentals and design grinding processes with predictive performance. The model regards grinding process as a time dependent process and an integration of microscopic interactions in the wheel-workpiece contact zone, including cutting, plowing, and sliding as well as other frictional interactions. And the grinding process control and design are in fact to manage and balance all these interactions. The fundamentals of microscopic interactions are analyzed and correlated to the grinding process input parameters and performance output.

1. INTRODUCTION

Grinding is a special machining process with large numbers of parameters influencing each other, which can be considered as a process where the thousands of irregular cutting edges interact with the workpiece at a high speed simultaneously. When perceived in this manner the grinding processes appear to be complex and managed only as a black art. However, irrespective of the choice of variables in the input categories, for every grinding process it is possible to visualize the basic microscopic wheel-workpiece interactions in terms of grain-workpiece interaction, bond-workpiece interaction, chip-workpiece interaction, and chip-bond interaction in Figure 1. Small changes in these 6 modes can have dramatic changes in the output of the system. Hence every abrasive machining process control is an effort to balance between cutting (surface generation) and tribological interactions of plowing/sliding while eliminating all the other frictional interactions [1]. And proper measurement and analysis immensely help application engineers in such strategic management of the grinding processes.

Moreover, grinding processes exhibits a strong time dependent characteristic, which is a combination of all microscopic interaction changing as a function of time. In industry where grinding power signal is widely measured for process monitoring, while the wheels get worn, loading, or glazing, the power curve will show a steady and gradual change as in Figure 2. Superimposing the power profiles of cycle 5 and cycle 1 makes the change visible, as shown in Figure 3. Within one individual grinding cycle which consists of several segments: rough, semi-finish, finish, spark out, etc. the MRR-Power draw can be obtained by curve fitting into a straight line. And the MRR-Power draw change from cycle 1 to cycle 5 tells the “inside story” of the grinding process. An in-depth analysis of

* Xuekun Li: Tel.: (0001) 508-831-6167; Fax: (0001) 508-831-6412; E-mail: xuekunli@wpi.edu
the MRR-Power draw, in Figure 3, leads to the decomposition of the power in terms of threshold and cutting components and other time dependent components. Each one of these components in turn is associated with specific aspects of the microscopic interactions, as well as the wheel properties alteration leading to such interactions. Figure 3 indicates a qualitative understanding of the MRR-Power draw change, which could predict grinding wheel surface conditions but still insufficient in providing an explicit solution for grinding optimization. And quantification of this power curve superimposition and MRR-Power draw in terms of the microscopic interactions and their change is a key aspect of managing modern grinding processes.

Figure 3: Superimposition of grinding power signals and its correlation with microscopic interaction modes

2. LITERATURE REVIEW

The literature on grinding process modeling is rather extensive and it would not be possible to cover it in any detail. As grinding force contributes almost all aspects of grinding process output, only pertinent literature dealing with force modeling is covered. S. Malkin [2] decomposed the grinding force into chip formation force, plowing force, and sliding force. The chip formation energy was related with the melting energy for iron, which was about $u_{ch}=13.8 \text{ J/mm}^3$. And the tangential plowing force per unit width was estimated to be 1N/mm for steels. Sliding was associated with rubbing of dulled flattened areas on the abrasive grain tips (wear flats) against the workpiece surface. Thus the grinding force was a summation of all these components. Inasaki [3] measured the cutting edges by counting the peak points on wheel surface. The cross-section area was automatically calculated in his simulation software for calculating the force acting on each single grain. The integration of force on all cutting edges gave the grinding force in global scale. Chen and Rowe [4] modeled a grinding wheel surface with statistical methods. And the single grain cutting force was regarded comparable to indenter-specimen interaction in Brinell hardness test in the absence of friction. The kinematic simulation generated the active grain number and cutting force on each grain. Badger and Torrance [5] used both Challen and Oxley’s 2D plane-strain slip-line field theory and Williams and Xie’s 3D pyramid-shaped asperity model to calculate grinding force on each single grain. Hou [6] incorporated the random nature of grain distribution into their work. The dynamic grinding force was formulated as the convolution of a single-grit force and the grit density function. All the literatures suggest the primary modules for a grinding process model should include a grinding wheel model, kinematics model, and single grain cutting model. However, the chip-workpiece, chip-bond, bond-workpiece interface and the time dependent properties of grinding process are
overlooked in current research. For such reasons, a grinding process model is in demand to quantify the significance and change of each single microscopic interaction as a function of time.

3. **Structure of the Grinding Process Model**

   ![Figure 4: Framework of the Grinding Process Model](image)

   The understanding of grinding processes in terms of time dependent microscopic interactions indeed shed light on the principles for the modeling. First of all, the change of the wheel surface conditions is the fundamental cause of the time dependent behavior of grinding. Therefore, a grinding wheel model is a prerequisite for grinding process modeling, through which the microscopic wheel properties and their change as a function of time can be presented. Secondly, in order to specify and quantify the 6 interaction modes, some criteria should be deduced for the identification and modeling of each mode. The output of each single interaction mode, such as force (or power) consumption, heat source generation, should be correlated with the input parameters in the microscopic interaction model. Thirdly, to determine the input data for microscopic interaction model, a kinematics model is necessary, from which the contacting condition of each interaction can be specified. Meanwhile, in the kinematics model, the integration of the output force (or power) provides the grinding force (or temperature) in macro-scale, and the heat source that is discrete in nature can be deducted from the microscopic force. In total, the time dependent grinding process modeling can be broken down into 3 levels in Figure 4:

1. A grinding wheel model, which describes both surface topographical and mechanical properties.
2. The microscopic interaction model, which serves to categorize and quantify each microscopic mode.
3. A kinematics model, which provides the contact condition for each mode and integrates the output data from the microscopic interaction model.

### 3.1. Grinding Wheel Model

Currently, there exist two popular approaches for grinding wheel modeling. One approach is to use pure mathematical methods to simulate the wheel surface. Alternatively, the other is to apply statistical approaches to solve this problem considering random distribution of grains on the grinding wheel surface [7]. However, the pore volume and the mechanical properties of the wheel, which are critical to the grinding process, cannot be obtained from all the reported methods.
In order to provide a virtual grinding wheel morphology which is equivalent to a real product in terms of topography feature as well as mechanical features, a through-the-process modeling method is proposed. Our idea is to utilize mathematical methods to intimate each wheel fabrication step, from raw material mixing to final wheel dressing. Not only the composition of wheel, such as grain size, grain shape, grain fraction, and bond fraction, but also the mechanics, and bond material diffusion during wheel firing are considered. After dressing simulation, the virtual wheel surface should bear resemblance with the real products in terms of static grain count, protrusion height, effective pore volume, and local wheel hardness, as indicated in Figure 5.

Figure 5: Framework (a) and procedure (b) of grinding wheel modeling

3.2. MICROSCOPIC INTERACTION MODEL

**Grain-Workpiece Interaction: Cutting, Plowing**

Cutting and plowing are the most fundamental interactions in grinding, which modify the workpiece surface directly and dominate the material removal efficiency. Moreover, the chip generation in microscopic cutting also contributes to the chip/bond interface and chip/workpiece interface. Meanwhile, the surface modification by one grain influences the material removal of the successive grain, as indicated in Figure 7 [8]. Therefore, mechanisms of cutting and plowing at microscopic level should be established for comprehensive understanding of grinding. Although a number of grinding experiments with a single abrasive grain were conducted, it is still quite intricate to establish the mechanisms in 3D due to the measurement difficulties of force, temperature and workpiece material deformation. On the contrary, Figure 7 indicates finite element models and packaged FEM software are capable to describe metal cutting processes explicitly. Therefore, there are great possibilities that finite element modeling can
be applied to investigate the single grain material removal under a wide range of grinding conditions. This can clearly quantify the force (or energy) consumption, chip generation mechanism, as well as localized material deformation, which are difficult to acquire based on only the common sense of grinding and single grain test. In this research, a commercialized FEM software package AdvantEdge™, which incorporates the thermo-mechanical properties of material, is employed for single grain material removal understanding.

In grinding, an abrasive grain can be considered to be an inverse cone shape or pyramid in Figure 8(a), and it may vary from different wheel specifications. During grinding, one abrasive grain seldom fully engaged with the workpiece, instead it will only contact partially with the workpiece, as indicated in Figure 7. Then, at the moment \( t \), the force consumption can be expressed as a product of specific cutting force times the grain-workpiece engagement cross-section area \( A(t) \) [3]. In addition, Figure 8 indicates that the specific cutting force is no longer a constant according to micro cutting theory, which should be described as a function of grain-workpiece engagement depth \( d \). The side flow formation for each single grain in cutting and plowing are also need to be considered, as the side flow geometry will affect the material removal of the successive grain. The side flow shape is considered to be a sphere cap, which is characterized by the width \( b \) and height \( h \). The chip volume generated during a time interval \( \Delta t \) can be derived for loading force calculation, which will be explained later in this paper. Through the FEM simulation, the force consumption, side flow geometry, and chip volume generation for each grain-workpiece contact couple can be deducted from following equations, as indicated in Figure 8.

\[
\begin{align*}
F &= \text{Specific Force} \cdot A(t) \\
\text{Specific Force} &= f(d) \\
F &= f(d) \cdot A(t) \\
b &= f(v, d, \text{grain shape}, t) \\
h &= f(v, d, \text{grain shape}, t) \\
\text{chip volume} &= f(b, h, \text{grain shape}, t) \cdot v \cdot \Delta t
\end{align*}
\]

**Grain-Workpiece Interaction: Sliding**

Figure 9 shows the grain-workpiece sliding occurrence when wear flat is developed on the grain tips. The area of wear flat gradually increases with grinding time and the rate of growth depends on the grain-workpiece combination, grinding parameters and the environment parameters. With the growth of wear flat, both the tangential and the
normal forces increase, thus resulting in further increase in grinding energy consumption, grinding temperature and thermal damage [2]. The total wear flat area, which is the summation of wear flat area on each grain tip, is found to be in linear relationship with the grinding force [9]. Considering the proportional relationship between the grain-workpiece friction force and grain-workpiece contact area, Equation 7 shows the sliding force (power) consumption.

\[ F_{G-W} = \mu_{G-W} \cdot \tilde{p} \cdot A_{G-W} \]  

Where, \( \mu_{G-W} \) is the friction coefficient between grain and workpiece material;
\( \tilde{p} \) is the pressure on the interface, which can be derived from previous cutting simulation;
\( A_{G-W} \) is the area of grain and workpiece contact.

According to the tool wear model developed by Usui [10], the wear flat development during grinding can be estimated as a function of time as in Equation 8.

\[ \frac{dA_{G-W}}{dt} = C \cdot \delta_n \cdot V_s \cdot \exp\left(-\frac{\lambda}{\theta}\right) \]  

Therefore, Equation 9 shows the calculation of the sliding force, which is equivalent to the glazing force.

\[ F_{G-W} = \mu_{G-W} \cdot \tilde{p} \cdot C \cdot \delta_n \cdot V_s \cdot \exp\left(-\frac{\lambda}{\theta}\right) \cdot dt \]  

![Figure 9: Grain-Workpiece Sliding in Grinding](image)

**Chip-bond and Chip-workpiece Interaction**

Chip-bond and chip-workpiece friction, absent in any other cutting processes, is one key area that differs grinding from cutting. These interactions usually happen associated with wheel loading, which is one of the undesirable phenomena in grinding. As wheel loading increase, additional energy is consumed due to the increased friction. Loading is the criterion for wheel dressing with fine grinding in 15% or even higher [11]. Wheel loading can be defined as accumulation or adhesion of grinding chips at the inter-grain space, as indicated in Figure 10.

Therefore, it can be inferred that the relationship between chip volume generated by the grain and pore volume in front of the grain is likely to influence the tendency for loading. Aside from the chemical effect, this can clearly be avoided by appropriate choice of grinding and wheel parameters. One possible solution without reducing grinding efficiency is to use wheel with high porosity or improved porosity shape for easier chip flow [12]. For this understanding, the loading force (power) consumption can be modeled as a function of ratio between leftover chip volume and pore volume, which can be described as:

\[ F_{B-W} = \mu_{avg} \cdot \tilde{p}_{chip} \cdot \left(\frac{V_{chip}}{V_{pore}}\right) \]  

\[ V_{chip} = \emptyset \cdot \int_{t_1}^{t_2} chip \, volume \, dt = \emptyset \cdot \int_{t_1}^{t_2} f(b, h, grain \, shape, t) \cdot dt \]  

where, \( \mu_{avg} \) is the average friction coefficient for chip-bond and chip-workpiece interface;
\( \tilde{p}_{chip} \) is the pressure in the interface, which is associated with the wheel hardness;
\( V_{pore} \) is the effective pore volume in front of a contacting grain;
$V_{\text{chip}}$ is the chip volume remaining in the pore in front of the grain, which is the summation of chip leftover from previous cuts and the chip generated by current cut.

$\phi$ is related with the cleaning efficiency of the coolant. Smaller $\phi$ is for higher pressure coolant, which can help evacuate the chip clogging in the pore more effectively while reduce $V_{\text{chip}}$ and the loading force consequently.

**Bond-workpiece Interaction**

Bond-workpiece is another key area that differs grinding from cutting. As grain wears or breaks down from the bond material, some of bond material rubs against the workpiece material consuming energy and as a result raising the specific energy requirement and heat generation, as shown in Figure 11. The bond-workpiece friction seems insignificant in conventional grinding, however, would play an important role in superabrasive machining where the metal bond is used as bonding agent [13]. The calculation of friction force between bond and workpiece material is similar to grain-workpiece sliding, the proportional relationship between the bond-workpiece friction force and bond-workpiece contact area still applies. Therefore, the bond-workpiece friction force can be expresses as:

$$F_{B-W} = \mu_{B-W} \cdot \bar{p} \cdot A_{B-W}(t)$$  \hspace{1cm} (12)

Where, $\mu_{B-W}$ is the friction coefficient between bond and workpiece material;

$\bar{p}$ is the strength of the bond, which is associated with the wheel hardness;

$A_{B-W}$ is the contact area of bond and workpiece contact.

3.3. Kinematics Model

The kinematics model serves to simulate the wheel moving against the workpiece under the specified grinding condition, which provides the number of contacting grains, contact cross-section area for each grain, and contact area of bond-workpiece interface, as shown in Figure 11. To determine the time dependent properties in grinding, the kinematics simulation is performed as an iteration procedure. During each iteration interval $\Delta t$, the wheel surface move relatively respect to the workpiece complying with the grinding parameters. The material removed by the simulated wheel sample can be regarded equivalent to a triangular shape in cross-section, as indicated in Figure 11. The height $h_m$ and length $l_c$ are corresponding to the maximum chip thickness and contact arc length, respectively, which can be derived analytically from existing literatures [2]. Both wheel and workpiece surface conditions are imported from previous simulation step, based on which the wheel-workpiece contact mode is calculated. Through calling the microscopic interaction models, the force consumption for each single contact couple can be obtained. Integration of the all the microscopic force gives the grinding force (power) consumption in global scale, which also gives a discrete heat source moving along the workpiece surface for future grinding temperature calculation.
Grinding Force = Cutting force + Plowing force + Sliding force + Loading force + Bond_Work force \hspace{1cm} (13)

4. Potential Applications

As a whole, the grinding process model enables the decomposition of grinding force components as a function of time. Since grinding force components are associated with the grinding wheel surface property change, the grinding process model helps predict the wheel surface evolution for grinding diagnoses and optimization. Furthermore, the grinding process model enables the calculation of grinding force (or power) for a cycle, which consists of several segments: rough, semi-finish, finish, spark out, etc. Therefore, the grinding process design can be carried out proactively while eliminating ‘trial and error’. In addition, the grinding wheel model itself can be used to guide the development and optimization of grinding wheels.

5. Conclusions and Future Research

The grinding process model framework based on the understanding and analysis of the time dependent microscopic interactions is developed, and the modules that constitute this model are described in detail. This model enables a quantitative description of the “inside story” in the grinding zone through separation and quantification of the 6 microscopic interaction modes. Further developments of this model include incorporation of different grinding processes, such as slot grinding, and profile grinding, application of more efficient computation algorithms.

ABSTRACT

Low-cost polymer polytetrafluoroethylene (PTFE) was used to fabricate a 1.5ml micro-bioreactor for the production of microbial surfactant (detergent). The choice of PTFE was attributed to the high permeability to gases, low cost and the ease with which it can be sterilized under steam or chemicals. A model microbe Pseudomonas aeruginosa DS10-129 was used in this study. The progress of fermentation/bioprocess was monitored by comparing the growth of the organism in a micro-bioreactor, conventional bioreactor and shake flask methods. Under the micro-bioreactor conditions used Pseudomonas aeruginosa DS10-129 produced 106g/ml of effective biosurfactants within 16h of incubation that reduced the surface tension of the culture medium to 27.9mN/m and emulsified kerosene by 71.30% that showed promising applications in enhanced oil recovery. A green pigment, pyocyanin was produced during the exponential phase, while biosurfactant production was observed during stationary phase of growth. The pigment showed antibiotic effect on various bacteria like Bacillus subtilis, Staphylococcus aureus, Staphylococcus epidermidis, Pseudomonas teessidea and Pseudomonas clemancea. The results obtained shows that the growth pattern and the production of biosurfactant and pyocyanin in the micro-bioreactor are comparable to those obtained by using the shake flask and the conventional fermentation (batch fermenter) methods. Hence the low-cost micro-bioreactor can perform the same functionality as the conventional bioreactors.

1. INTRODUCTION

The development of micro-total analytical system (µTAS) has seen researchers focussing on scaling down expensive grandiose equipment to miniature scale with the overall aim of improving throughput, enabling fast analysis, optimising operations and cutting down on resources. Currently, microfluidic systems are being employed to study diverse processes such as bioprocessing developments, chemical synthesis, clinical diagnostics and genetic engineering.

Research has shown that microfluidic systems are a promising technology that has the potential to improve analytical performance, reduced laboratory safety requirements and costs, shorter analyses time and above all reduced reagent use [1]. Bioprocessing operations such as fermentation has been widely used to realize a number of products of economic importance such as antibiotics, vaccines, therapeutic proteins and many others. However the current mode of operation for these processes is the use of conventional stirred tank bioreactors with typical volumes between 0.5 and 10 l and shakes flasks [2].

These conventional systems have some limitations which includes among other the following: (i) conventional bioreactors are bulky; they consume a lot of resources thereby making bioprocessing an expensive undertaking. (ii) process steps are labour intensive to operate and maintain i.e., sterilizing, cleaning, assembling and dissembling of the bioreactor components, (iii) generation of large volumes of metabolic waste, which may be toxic to natural ecosystems and costly to manage, (iv) sampling process is prone to contamination due to the magnitude of the manipulations that are made, and may result in changing the experimental conditions and (vi) systems are not amenable to performance of experiments in parallel. To mitigate these constraints novel studies on designing and fabrication of miniaturized bioreactors have been documented.
To date a number of different microbioreactors have been reported in literature [3], [4], [5], [6]. These reports have shown that low volume, disposable, microbioreactors with parallel processing operations, and integrated real time measurements are a promising tool in high throughput bioprocessing developments. For example previous work by [3],[6] have shown that microbioreactors provide unique environments, which are ideal for rapid and efficient biosynthesis due to the scale dependence of thermal and mass transfers.

A portable anaerobic microbioreactor to study the optimum growth conditions for the methanogen, *Methanoseta concilii*, a methane-producing obligate archaeabacterium was developed [7]. This work demonstrated the ability of *M. concilii* to grow in the bioreactor microfluidic channels under optimum conditions of temperature, nutrients and pH. Recently microbioreactor arrays developed for controlling cellular environments in human embryonic stem cells [5]. The system uses a simple and novel practical system that couples a microfluidic platform with an array of microbioreactors. A 150μL, well mixed polymer based microbioreactor with integrated optical measurements also developed [8]. In this bioreactor mixing was achieved by magnetic stir bar and fluorescent sensors were integrated for online measurement of pH and dissolved oxygen. It was shown that the behaviour of *E.coli* fermentation in a microbioreactor was identical to the results obtained in a conventional bench scale bioreactor. In their sterling work [3] pioneered and demonstrated online measurements of optical density (OD), pH, and dissolved oxygen in a 1L fermentor. In another development a miniature bioreactor with a working volume of 6mL has also been reported [9]. Oxygenation was achieved by sparging while mixing was enhanced by an impeller.

*Diluzio et al* used microfluidics to study the interactions of motile cells of bacteria with surfaces[10]. They observed that hydrodynamic interactions between cells and the walls of the channels cause the cells to swim preferably on one side of the channel. On the other hand, [11] and the Quake group developed a multi-compartment microfluidic bioreactor composed of PDMS peristaltic pumps and microvalves. The device was fabricated using soft lithographic techniques and was used for sustaining the long term controlled growth of a small population of *E. coli* in the microfluidic loop based bioreactor.

A detailed review [12] highlights the current practices and future opportunities in miniature bioreactors. The review focuses on the use of microbioreactors and their application as an effective tool in bioprocessing, media developments and strain improvement to process optimisation. In view of these developments it can be seen that microbioreactors have the potential to replace labour intensive shake flask and conventional bench bioreactor methods in the screening phase of biological experiments.

In this work we describe the design of a batch fed microbioreactor made from Polytetrafluoroethylene (PTFE) tubes of 0.8mm in diameter with a working volume of 1.5ml. The choice of using PTFE was attributed to its permeability to gases, less costs and the ease with which it can be sterilized. To assess the performance and effectiveness of the microbioreactor, we used *P. aeruginosa* DS10-129 sampled from sites contaminated with diesel as the model microorganism [13] [14] [15]. In this work, we report the fermentation of *P. aeruginosa* in the microbioreactor, fermenter and shake flask methods in terms of growth and productions of extracellular metabolites (pyocyanin and biosurfactants).

2. MATERIALS AND METHODS

2.1 MICROBIOREACTOR DESIGN

The microbioreactor was made from a synthetic polymer polytetrafluoroethylene (PTFE). A PTFE tube (length 3 m 0.8 mm diameter) was made into coils of diameter 4.2 cm to give a microbioreactor of working volume 1.5 ml (Fig 1).

2.2 MICROORGANISM AND CULTURE MEDIUM CONDITIONS

*Pseudomonas aeruginosa* DS10-129 (AM419153) sampled from diesel contaminated sites [13] [14] [15] was used for all the experiments. To promote pyocyanin production, DS10-129 was cultured in glycerol supplemented nutrient broth (GSNB) medium. The organism was regularly resuscitated in Glycerol Supplemented Nutrient Broth (GSNB) medium and working cultures were sub cultured on nutrient agar plates and incubated at 30°C for 18-24h. The composition of the Glycerol Supplemented Nutrient Broth (GSNB) medium was (g/l): Lab Lemco Powder 1.0, yeast extract 2.0, Peptone 5.0, Sodium Chloride 5.0, 30ml glycerol and 1litre of deionized water. The pH of the medium was adjusted to 6.5±0.2. Single colonies of DS10-129 taken from 18-24 hour cultures were used to prepare
inocula in sterile GSNB medium. The inoculated media was incubated in a rotary shaker set at 30°C and 150 rpm. When the optical density of the culture medium was between 0.8 -1.0, it was used to inoculate the GSNB media to give a starting optical density of 0.1 at 600nm. The inoculated media was also used to for the microbioreactor experiments.

2.3 **Fermentation in the Microbioreactor**

By using aseptic techniques, the sterile GSNB medium was inoculated with DS10-129 suspension to give a starting OD$_{600}$ of 0.123, equivalent to approx. 5.7 x 10$^8$ cells/ml. The inoculated media was withdrawn with a 5 ml syringe and mounted on a syringe pump (Razel Scientific, USA) and was used to inoculate the microbioreactor as shown in Fig. 1. After the inoculation procedure, the inlet and outlet ports of the microbioreactor were each connected to a 0.2 µm Whatman sterile syringe filter. This was to prevent contamination and allow diffusion of gases in and out of the microbioreactor. A total of three microbioreactors were prepared and inoculated in the same manner and allowed to run in parallel. The microbioreactors were incubated at 30°C with shaking at 150 rpm for 24h.

At predetermined intervals all the three microbioreactors had their contents sacrificed and monitored for cell growth by measuring the OD$_{600}$ of the metabolised GSNB medium. The metabolites produced by the organism were collected by centrifuging the culture broth at 8000g at 4°C for 20 min to remove bacteria. The supernatant was filtered through a 0.2 µm syringe filter, protected from light and kept refrigerated for subsequent analyses.

2.4 **Fermentation in the Fermenter and Shake-flask**

Parallel batch fermentations of DS10-129 to monitor the production of pyocyanins and rhamnolipids were carried out in a fermenter and shake-flask under agitation for 120 h. A 7.5 l bioreactor (BioFlo 110, New Brunswick Scientific, USA) was filled with 3 l sterile GSNB medium and inoculated with a suspension of DS10-129 with optical density 0.8–1 to give a starting OD$_{600}$ of 0.123. The temperature, pH and agitation speed were maintained at 30°C, 7 and 200 rpm, respectively, but the levels of dissolved O$_2$ were not monitored. Samples of the metabolised culture medium were periodically withdrawn for OD$_{600}$ measurements and subsequent down-stream processing as described for the microbioreactor.

Similarly, a 250 ml conical flask containing 100 ml sterile GSNB medium was inoculated with DS10-129 and incubated at 30°C with shaking at 150 rpm. Samples were withdrawn periodically and treated as described for the other systems.

---

**FIG 1.** Schematic set up of the microbioreactor. The GSNB and the inoculum are introduced into the microbioreactor by a syringe pump as a batch feed. Sterile 2µm Whatman syringe filter are fitted at the inlet and outlet (when the syringe pump has been disconnected) of the microbioreactor. The purpose of the filters is to allow diffusion of gases in and out of the microbioreactor.
2.5 Pyocyanin Production

The presence of pyocyanins was detected by visual observation of a green pigmentation produced by the organism in the nutrient broth culture.

2.6 Inhibitory Effect of Pyocyanin

The following microorganisms S. epidermis, B. subtilis, Staph. aureus, Micrococcus luteus, Pseudomonas teessidea PR6.5 (AM419154), P. clemancea PR22.1 (AM419155), P. aeruginosa DS10-129 (AM419153), Aspergillus niger and Sacc. cerevisiae were used in this study. The inhibitory effect of pyocyanins was determined by using the agar diffusion method. 60 μL suspensions of each microorganism with an OD of 1 ± 0.2 were used to inoculate 20 ml of sterile molten Antibiotic Medium Number No. 1 Agar (ANTBA1) respectively. The composition of ANTBA1 was (g/l): peptone 6; tryptone 4; yeast extract 3; Lab-lemco powder 1.5; glucose 1; and agar 11.5. The agar plates were allowed to solidify at room temperature and three holes of 7 mm diameter were punched on the solidified inoculated media using a cork borer. 60 μL of the concentrated cell free supernatant harvested at different times was added to the agar wells and incubated at 37°C for 18–24 h. For A. niger and Sacc. Cerevisiae, Sabouraud’s Dextrose Agar (SDA) was used and the plates were incubated at 30 ºC for 18–48 h, respectively. The suspension of B. subtilis was prepared from a culture that had previously been incubated for 5–7 days to allow for the formation of spores. The antimicrobial activities of pyocyanin against each organism were determined by measuring the diameter of the zones of inhibition using a pair of vernier callipers.

2.7 Production and Characterisation of Biosurfactants

The produced biosurfactants were detected by using the following quantitative and qualitative methods.

2.7.1 Quantitative Estimation of Rhamnolipids

The concentration of rhamnolipids in the sample was estimated by the Orcinol method [16][17]. The rhamnolipids concentration was quantified from the standard L-rhamnose calibration curve between 0 and 50µg/ml and the result expressed as rhamnose equivalents (RE) (mg/ml) by multiplying rhamnose values by a coefficient of 3.4, obtained from the correlation of pure rhamnolipids/rhamnose[17][18][19].

2.7.2 Surface Tension Measurements

The surface tensions of the cell free supernatant medium were measured using a Tensiometer (Kruss Digital Tensiometer - Model K9, Germany).

2.7.3 Determination of the Critical Micelle Concentration (CMC)

Critical micelle concentration (CMC) is the lowest concentration of the surfactant that is required to form micelles. When a surface is saturated with molecules of surfactants any more addition will result in the arrangement into micelles and this property is a characteristic feature of biosurfactants. The determination of CMC was performed by diluting the cell free supernatant containing the highest concentration of rhamnolipids and each sample was diluted up to 1: 512. The surface tension of the diluted samples was measured at room temperature (25°C) as described previously using a tensiometer.

2.7.4 Haemolytic Activity

The haemolytic activity of rhamnolipids was estimated by using agar diffusion method. Four equidistant holes of 7mm in diameter were punched on petri-dishes containing 5% Sheep Blood Agar. 60µl of the cell free supernatant extracts was introduced in each well respectively. The inoculated plates were allowed to stand at room temperature for 24-48h. The zones of haemolysis were measured for each system.
2.7.5 **METHYLENE BLUE AGAR ASSAY**

The concentration of anionic surfactants in aqueous solution was determined by the formation of an insoluble ion pair with cationic substances. The insoluble ion precipitates in the Methylene Blue Agar by forming a deep dark blue color against a light blue background using the cationic substance CTAB [20]. Rhamnolipids were identified by formation of dark blue hallow zones on a light blue background by agar diffusion method [19].

2.7.6 **EMULSIFICATION ACTIVITY OF RHAMNOLIPIDS**

The emulsifying activity of the cell free supernatant was determined by using the approach practiced by [21]. 2ml of supernatant and 2ml kerosene mixed and vortexed for 2 min. The mixture was allowed to settle undisturbed at room temperature for 24 hours. The height of the emulsion layer was measured after 24h to determine the emulsion index.

2.7.8 **INFRARED SPECTROSCOPY**

The molecular structure of the rhamnolipids was identified by using a Fourier Transform Infra red spectroscopy (FTIR) Perkin Elmer 100 series. The cell free supernatant was acidified to pH 2 by adding 2M Sulphuric acid to precipitate the rhamnolipids. The precipitated rhamnolipids were extracted with an equal volume of 2:1 dichloromethane/methanol. The organic phase was dried with anhydrous Sodium Sulphate (Na$_2$SO$_4$) to remove excess water and was evaporated to yield the pure rhamnolipids on a rotary evaporator (Buchi, rota vapor R-200 Germany) set at 60-70°C. 2-5mg of the concentrated rhamnolipids was characterized on the Perkin Elmer Spectrum 100series FTIR spectrophotometer.

3. **RESULTS AND DISCUSSION**

The growth profiles for *Pseudomonas aeruginosa* under the three different environments are shown in (Fig 2). The fermentation process in the microbioreactor was limited to 24h while for the conventional scale it was 120h. The progress of the batch fermentation process of DS10-129 in the bioreactor, shake flask and the fermenter was monitored by measuring the optical density of the spent medium. The generation time for *Pseudomonas aeruginosa* in the microbioreactor was slightly higher when compared with the other processes. This development could be attributed to the small cross sectional dimensions of the microbioreactor which results in rapid heat and mass transfer due to the large surface area to volume ratio. Production of pyocyanins was evident during the exponential phase (6 h) of growth of the organism in the bioreactors. Pyocyanin production showed a steady increase in concentration throughout the incubation period (Table 1). In view of this development the early production of pyocyanins could have been caused by an increase in temperature in the channels. Previous reports [22] have shown that the production of pyocyanin is dependent on increase in temperature.

Table 2. Quantification of biosurfactants produced by DS10-129.

FIG 8. Infrared Spectra of rhamnolipids: A = 3368.10 cm⁻¹ (OH free stretch due to hydrogen bonding), B = 2925.42-2856.40 cm⁻¹, (Aliphatic bond stretch CH₃ CH₂ and CH), C = 1737.33 cm⁻¹ (C=O stretch due to the ester functional group), D = 1455.52-1380.65 cm⁻¹ (bending of O-H bands in carboxylic acid group), E = 1300 – 1033.61 cm⁻¹ (C-O stretch due to ester functional group).
Results in Table 2 and Figure 4 show that DS10-129 produced effective biosurfactants that lowered the surface tension of GSNB from 58 to 27-30mN/m. The result of the critical micelle concentrations of the diluted samples in Figure 5 shows a reduction of surface tension of distilled water to about 30mN/m, indicating that the tension-active properties of the rhamnolipids produced have better prospects for industrial applications such as bioremediation.

Haemolysis of blood agar was first described [24] to screen the biosurfactants producing bacteria. [25] used the method to quantify the amount of surfactin produced by B. subtilis and demonstrated that the presence of the biosurfactants caused the lyses of the red blood cells in the agar. In this work the presence of biosurfactants in the samples was qualitatively detected by haemolysis of erythrocytes in 5% Sheep blood agar medium. The results show that the cell free supernatant collected from the bioreactors contained fairly large amounts of factors with haemolytic activity as shown by the diameters of zone of clearing on red blood cells in sheep blood agar in Figure 6 for the different sampling times.

Like all synthetic surfactants rhamnolipids consists of a polar head and non polar tail groups, when they combine with different cationic substances, such as Cetyl Trimethyl Ammonium Bromide (CTAB) to form insoluble ion pairs in aqueous solution, which precipitates as dark blue zones against a blue background in the methylene blue agar [21]. The result shown in Figure 7 indicates the production of effective rhamnolipids by DS10-129, which precipitates the CTAB in the Methylene blue agar. Several previous studies have shown that rhamnolipids are normally produced during the stationary phase of growth [4][26][27][25]. The size of the zone of inhibition was proportional to the amount of biosurfactants present in the sample.

Results in Table 2 shows that the biosurfactants produced by DS10-129 has good emulsifying activity. The higher emulsification index corresponds to the complete emulsification of the oil phase. Previous reports [28] have shown that a good bioemulsifier is the one that has an index of 50% and more. The results suggest that the quality of biosurfactants produced by DS10-129 has higher emulsifying activity and would be very useful in bioremediation work. The production of rhamnolipids was confirmed by FTIR spectroscopy. The FTIR spectrum of the rhamnolipids is shown in Figure 8. According to the results of the infrared spectra in Figure 8, the rhamnolipids extracted belongs to the glycolipid group, which is made up of aliphatic acid and ester. The results obtained are consistent with the structure reported by [29] consisting of aliphatic acid and the glycolipid moiety.

4. CONCLUSION

The results obtained from the work have demonstrated that Pseudomonas aeruginosa DS10-129 is capable of producing extracellular secondary metabolites such pyocyanins and biosurfactants when cultured in a microbioreactor environment.

CONTACT AREA, PRESSURE DISTRIBUTION, AND MECHANICAL STABILITY IN EXTERNAL ARTHRODESIS OF THE ANKLE JOINT

C.J. Connor,1* S. Hodgson2 and F. Nabhani2

ABSTRACT

The ankle joint is often affected by arthritis, giving a joint that is painful, stiff, and restricts movement. This can result in a huge loss of mobility for the sufferer. Unlike replacement of the hip, the replacement of a diseased ankle joint is not as straightforward and the outcomes do not reach the same success levels. The preferred surgical choice is arthrodesis, a procedure whereby the two bones forming the joint are fused together to eliminate the joint and hence pain. The success of the procedure is dependent upon several factors, two of the most significant being the levels of contact area and pressure achieved during the compression period, during which bone growth occurs across the two bones being compressed together. These factors influence joint stability and micromotion at the bone to bone interface during this growth phase.

This study investigates the levels of contact areas and pressures that can be achieved for different arthrodesis variables. These variables include the joint shape, which can be curved or flat, and the position of the compression pin within the talus, namely anteriorly or centrally positioned with reference to the talar dome. Influence of the Achilles tendon in joint stability is also investigated.

A test rig was developed allowing load/deflection curves to be determined for various configurations of these variables. Models representing the bones under consideration, together with pressure sensitive film, allowed measurement of contact areas and pressures within the joint under compression, achieved using pins and instrumented compression rods.

Results indicate there is little significant variation in contact area and pressure for the different shaped joint cuts, however, if the talar pin is placed in a more anterior position then the contact area can be improved over a centrally positioned pin. Anterior pin placement also gives increased resistance to motion and mechanical stability. It has been established that the arthrodesis construct is especially weak in terms of rotation about the tibial axis, and the results from this study indicate that through the use of a curved joint shape the resistance to this motion can be improved greatly.

1. INTRODUCTION

The ankle is a joint that is often adversely affected by arthritis, resulting in a painful joint with limited mobility. One of the standard procedures for alleviating this pain is arthrodesis of the ankle, which involves fusing together the two major bones that form the ankle joint.

A number of techniques are available in order to perform this procedure, the first recorded technique having been documented by Albert in 1882 [1]. These various techniques include the use of internal screw methods and external compression using pins. Whilst these techniques have been documented and successfully performed for many years, there has been little investigation into the biomechanical factors that determine their success rate and their potential effect upon the joint during the initial bone growth phase.

This study investigated the effect of two variables upon the external arthrodesis structure. The particular fusion technique considered obtained compression at the joint site by inserting one horizontal pin through the talus and another horizontal through the distal tibia, and using compression clamps to force the two pins, and hence the joint, together. In 1951 Sir John Charnley proposed that optimum ankle fusion could be attained by cutting opposing...
bones in a flat shape, and that by positioning the talar pin in an anterior position, the Achilles tendon force would result in an even anterior-posterior compression force distribution [2]. Recent variations on this theme have sought to address the weakness of such a technique, especially when subject to axial rotation loads, by cutting the bones in a curved shape (i.e. attempting to retain approximate original joint shape) [3,4]. This study investigated the effect of pin position and joint shape upon the pressure distribution attained within the joint and its resistance to motion, both factors being critical to successful fusion, as any motion at the joint site will damage any potential bone growth taking place across it.

The vast majority of biomechanical studies in this field have compared the success of various arthrodesis techniques against one another [5,6], with only more recent studies investigating the effects of different physical variables available during the procedure [4]. This study used a combination of internal joint pressure measurement, together with bending and torque deflections at the joint site to determine the likely effect upon joint stability of these variables. The use of finite element models to evaluate the stability of arthrodesis constructs has only recently been applied to internal compression arthrodesis techniques only [7].

The use of pressure sensitive film to determine pressure levels within joints has been well documented in relation to biomechanical studies [8], and this technique was used to determine pressure levels within the joint under compression.

2. MATERIALS AND METHODS

A 3D CAD system was used to develop models of the talus and distal tibia to be constructed from CT scan data obtained of an adult male. These models were resected within the CAD environment to generate suitable flat and curved shaped models of both bones using appropriate surgical advice. Positions of compression pin holes were also mapped on to these computer models. Data from these models was then output and a CNC machining system used to reproduce approximations of these models as physical entities, as illustrated in Figure 1.

![Physical Models](image)

A test rig was developed that would allow the simulation of external arthrodesis. The talar model could be fitted into a component representing the foot, and the horizontal talar compression pin inserted through it. The model representing the distal tibia was mounted in a plate above this in the frame of the test rig. The contact between the lower tibial surface and the superior talus surface allowed the formation of the ankle joint to be simulated. Instrumented compression clamps were then used to apply known compressive loads to the joint, by compressing the talar model against the fixed tibial surface. Compression could also be applied at the rear of the foot component via an instrumented compression rod between the rear of the foot component and the upper frame of the test rig.
Pressure sensitive film (a film that changes colour in relation to applied pressure) was inserted into the joint between the two models and the joint compressed to predetermined levels in order to record pressure distribution within the joint. This procedure was first performed for a flat joint shape with compression being achieved using an anteriorly positioned talar pin. The pressure sensitive film was then removed from the joint in its expended state for evaluation. The flat shaped model was then used again, with a centrally mounted talar pin. The process was then repeated using the curved shaped models, with the pin again being positioned in both the anterior and central positions. These studies were performed firstly without any Achilles tendon compression, and then repeated with the application of an Achilles tendon compressive load.

The pressure sensitive film that had been exerted to compression was scanned, converted to greyscale values and computer programs used that would count the number of pixels and their corresponding greyscale value in order to determine joint contact area and average pressure. Known calibration charts were used to quantify these figures. An example of this output is displayed in Figure 3.

The mechanical stability of these arthrodesis constructs was then measured by compressing the joint as previously, but without pressure sensitive film in the joint. External loads were then applied in order to induce motion at the ankle joint in the various directions that the actual joint can move in, namely
plantarflexion/dorsiflexion, inversion/eversion, and internal/external axial rotation. The level of displacement in such directions was measured in response to increasing loads, allowing load/deflection data to be obtained for the various directions.

3. RESULTS

3.1 PRESSURE DISTRIBUTION

It was discovered that only small differences exist in the levels and distributions of pressure within the joint far varying pin positions and joint shape. Following a MANOVA analysis (p=0.05), it could be stated that:

When the opposing bone surfaces are cut with flat shapes, the optimum contact pressure was obtained with an anterior pin and an applied Achilles tendon load, and that in all cases the Achilles tendon load increases the joint pressure.

When the curved joint shape is retained, optimum contact pressure was obtained with an anterior pin. Again, the Achilles tendon load increases pressure in all cases when a curved shape surface is maintained.

Overall it can be stated that for curved cut models, pressures remain in the main constant with slight improvements possible when using anterior pins. For flat models, overall pressures are slightly higher than for curved joint shapes, and increase even more when using anterior pins.

These results are illustrated in Figure 4.

![Figure 4: Pressure Distribution Results](image)

3.2. MECHANICAL STABILITY

Figures 5 to 7 show a summary of the results of maximum deflection obtained for the various stability tests following one-way ANOVA analysis (p p=0.05). The matching opposite motions i.e. dorsiflexion against plantarflexion were found to follow a similar pattern to the data shown and so only results for one of the motions are provided.
The mechanical stability tests demonstrated that the joint deflection for directions in which physical opposition to motion exist due to the physical formation of the joint, such as plantarflexion/dorsiflexion and inversion/eversion, the deflections recorded were very small (below 0.3mm). These did however illustrate that the Achilles tendon was important in resisting motion and balancing the joint. These tests showed that the weakest combination of variables occurred when a central pin was combined with a flat joint shape, the optimum scenario being an anterior pin and curved joint shape. In between these two extremes came the other combinations i.e. flat with anterior pin and curved joint with a central pin.

The most significant findings however came in the rotational tests where it was clearly demonstrated that a curved joint shape had a major effect upon resistance to motion, which was noticeably larger than in the other loading directions. When coupled with an anterior pin noticeable improvements in resistance to motion were found. The worst situation was again a flat cut with a central pin. The deflections recorded during the rotational tests were in the order of magnitude almost 10 times larger than those measured during the inversion/eversion and plantarflexion/dorsiflexion tests, illustrating the importance of this load factor in resistance to joint micro-motion, and the weakness of such constructs in relation to this type of motion.
4. DISCUSSION

A number of biomechanical studies have sought to define the optimum technique for arthrodesis. These studies have succeeded only in confirming that specific pin, screw or plate configurations performed better than one another. Miller [6] investigated the effect of joint shape, but could not find any statistical differences between flat cut and contour preserved specimens, possibly due to the low number of cadaveric test specimens available. The lack of availability of consistent cadaveric specimens led to this study using polyurethane models to represent the bone. Further validation of this experimental work is currently being performed using finite element modelling, and the results from these experiments correlate well with those found in other finite element studies [7].

This study has also considered a situation of perfect joint congruency, with solid bone material that is not affected by degeneration, however in most rheumatoid cases requiring surgery the joint surfaces remain intact within a painful joint due to cartilage destruction. Investigation into the application of different material properties representing poor bone stock would be a useful addition to this work.

5. CONCLUSION

It can be seen from Figure 4 that the pressure sensitive film tests showed only slight variations in pressure across the joint for different pin and joint shape combinations. They did however illustrate the importance of considering the Achilles tendon during such experiments. It was discovered that marginally better results were obtained using an anterior pin position, with little difference between curved and flat joint shapes.

The mechanical stability tests however clearly illustrated the benefits that could be obtained in resistance to motion across the joint when using an anterior pin and curved joint shapes. This was especially true for rotational resistance, which is the major weakness of arthrodesis constructs. Whilst there may be a slight reduction in joint contact pressure when curved models are used, these differences are insignificant in comparison to the additional joint stability that can be afforded in rotational displacement when such surface shapes are retained.

These findings have been further substantiated by additional 2-dimensional finite element studies that have been performed, and confirm the hypothesis that a curved shape and an anterior pin will give greater stability during the arthrodesis recovery period, improving likelihood of fusion.

Ongoing work includes the development and utilisation of 3-dimensional finite element models of these joints in order to further study the contact across this joint both in terms of pressure and displacement under load during compression.

REFERENCES

ABSTRACT:
Whiplash injured patients often complain of pain in the shoulders following rear impact, it is the aim of this investigation to assess the cause and effect of these pains and advise on corrective measures. A 3D model was generated and a finite element analysis was performed simulating a crash situation to assess and define this injury more clearly. The model displayed a clear proximal force resulting from the impact scenario which created an increased loading on the supraspinatus. This injury occurs when a driver sees a vehicle approaching from behind and braces himself/herself for the impact locking the elbows and pressing against the steering wheel. This causes the shoulder centre to become posteriorly and proximally located so that during distal impact, large forces are impacted on the supraspinatus and subscapularis tendons. It is hoped that with the information gathered from this study that these injury's will be diagnosed earlier and lead to better long term recovery.

1. INTRODUCTION:
The number of rear impact crashes in the UK is alarming given the relatively low protection drivers are offered in current Automobiles. According to A. P’erez del Palomar in 2007 Rear-end impacts account for more than one-third of vehicle Accidents [1]. Simpson (1994) found that 16.1% of road crashes occurred from a rearward direction. This figure may be conservative since inclusion in this study required a minimum claim of £202 [2]. Rear end impacts are most common at intersections where the struck vehicle is stationary or travelling slowly for a red light [2].

The normal recommended driver seating position is displayed in fig 1. This position maximizes control and safety while driving. The braced position as seen in fig 2 is when the hands are placed firmly against the steering wheel, elbows locked and the body pressed firmly back into the seat back. Bracing often also forces the body upwards in the seat to allow for full extension of the arms to the locked position, this action pushes the shoulders above the support of the rear of the seat. This is a natural reaction when the body is in danger.

Though the technology has been available since 1999 very few cars are fitted with rear impact sensors. During a frontal impact frontal sensor activate the deployment of air bags. This not only absorbs impact but is designed to force the hands off the wheel or at least bend the arms. This stops people locking elbows during impact.

The injury in question in this paper is a pain in the shoulder immediately after impact when hit from the rear in the braced position. The injury is often diagnosed as a nervous condition in accident and emergency or is treated merely with anti-inflammatory medication. This injury has symptoms similar to bracing injury’s occurring from referred pain from the neck; shoulder symptoms often arise from both sources. However there are cases reported by Frank [3] during clinical experience of people suffering pain and immobility 2-4 years after the injury occurs.

* Corresponding author: Tel.: (01642) 342482; E-mail: f.nabhani@tees.ac.uk
It is proposed that when a rear impact occurs, while in the braced position with the combination of the biceps, triceps and deltoid restricting forward joint motion and the glenoid restricting backward motion of the proximal humerus that the shoulder centre becomes posteriorly and proximally located putting large crushing forces on the supraspinatus and subscapularis tendons muscles. These muscles then scar which makes them more susceptible to tearing which leads to a greater build up of scar tissue in the joint. This supposition would seem concurrent with the cases detailed above where problems only arise 2-4 years after trauma [4]. The Stretching Institute [4] advise patients with muscle injuries that to prevent the buildup of scar tissue the injured area needs to be treated within the first 72 hours. If scar tissue develops it creates a weak spot in the muscle and loss of flexibility [4]. These are typical symptoms in cases of this rear impact shoulder injury as observed by Mr P L Frank.

It is reported by Frank [4] during his clinical experience that people who suffer from this injury tend to be males. This is probably attributed to males sitting with the seat further back and often with the seat more reclined making the locking of the elbows easier. This observation is supported by the findings of Parkin et al [5] who measured driver seating position on 1000 cars and noted that men tend to sit further back in their seats.

Given the high prevalence of rear impact crashes and the clear force applied to the upper limbs during impact it is important that drivers are properly protected during a crash situation. Euro NCAP (European New Car Assessment Program) however does not even consider shoulders in their testing “Neither arm carries any instrumentation in a crash test, the arms flail around in an uncontrolled way” [6].

It is often assumed that occupants with advance warning of an impending collision have fewer and less severe symptoms than those who are surprised by rear-end impacts [7]. However this currently unrecognized injury could change those statistics.

Aims:
1.) The cause of pain generated in the shoulder complex during reverse impact road accidents
2.) Loadings generated on the supraspinatus and subscapularis tendons.

2. METHODOLOGY:

2.1 EXPERIMENTAL MODAL

In this study a 3-Dimentional Finite Element Analysis (FEA) model will be generated to recreate the in-vivo mechanics of the glenohumeral joint during the impact phase of a rear impact automotive crash. FE models need a great deal of computational power, but can provide detailed information about tissue deformations and injury prediction. Multi-body models can also include many anatomical details while being computationally efficient. This makes them suitable for parameter variation and optimization analyses [8]. The value of FEA in modern prosthetic design and clinical testing cannot be understated. 3D in-vivo Models are accurate and reliable [9] providing opportunities for complex testing to be performed in almost any theoretical situation.

2.2 LOADING VALUES

The loadings to be applied to the Model are taken from previously generated research, this provides a accurate peer reviewed set of constraints for testing.

The moment generated by the contorting body is based upon findings by Golinski et al (2004) who proposed a moment of maximum value 1.5Nm based on sled experiments conducted by Steffan [10-11]. Measurements from real accidents were used in order to achieve realistic deceleration of the sled.

The model also uses the acceleration pulse suggested by Euro NCAP of 4.4 m/s applied to the seat [12]. This is the force generated as the seat is catapulted toward the steering wheel by the impact.

The rotor cuff will be treated as a constant 15N force across the joint [13]. This constant, evenly applied force is typical of tests of this type balancing the shoulder and recreating a basic loading similar to that provided within the joint.

It has been observed that Muscle tensing can change the effective stiffness and mass of a body segment or region [14]. A 338 per cent increase in thoracic stiffness (from 70 N/cm to 236 N/cm) was observed when the volunteers maximally tensed the muscles of their shoulders, thorax, arms, back, and neck [14]. In this light the shoulder joint will be treated as fixed restrained in the scapula-thoracic plane as any movement is heavily restrained by the surrounding musculature and the seat back.
It has been shown that the long head of the biceps and the deltoid muscle have an important role in the stability and support of the glonohumeral joint [15-17]. This is represented in the model using a 700kPa distributed force over the muscle contact areas. 700kPa is an approximated muscle force value used by R W Kent et al in their 3D FEA model for testing thoracic deflection described above [14].

### 2.3 Car Seat Model

An accurate modeling of the car seat is another essential aspect of rear impact investigation [12]. Car seats comprise of a backrest, a sprung centre and a foam cover. The material properties defined for the chair back were based upon data collected by Nicolas Bourdet et al (2007) in their design for a car seat model for rear end impact testing [12] See figure 3.

Figure 3. Table showing car seat back properties.

Golinski et al stated that only once the limit of seat back deformation is reached does the torso rapidly accelerate forward [11]. However due to the nature of the bracing position the torso is already forced firmly back into the seat to allow the elbows to lock fully (fig 2). For this reason it was determined to neglect the effects of cushioning in the seat during impact in this study as its presence is deemed negligible. The seat in the generated model forms a solid fixture behind the scapula which restrains the impact forces.

### 2.4 Shoulder Position

The dimensions of the shoulder complex were taken from CT scans produced for the Laboratory of Human Anatomy and Embryology, University of Brussels. These were used as they provide a high quality, previously tested, set of images.

There are no specific angles at which the arm can be said to be at as it depends on driver height, driving position and seat recline angle. The theoretical driver was selected to be a 50th Percentile Male Driver. As stated earlier this injury is most often detected in male drivers. The theoretical driver arrangement for this study can be seen in fig 4.

For the purposes of this study the humerus was said to be at an angle of 15º to the scapulothoracic plane shown as Y in fig 4.

Figure 4. Assumed Driver Seating position.

### 2.5 Shoulder Model

A threshold was applied to the CT images (1 slice per mm) and polylines generated around the model extremities 1 per slice.

The Shoulder complex was then modeled in IDEAS-nx12 (Siemens PLM). This allowed for modeling and finite element analysis to be performed in a single software package. The polylines generated were lofted together to create a solid model.
The model was Free meshed with 2.15983 mm Solid tetrahedral elements as shown in figure 5. Trabecular bone has not been accounted for in this study.

![Meshed Glenohumeral Joint](image)

Figure 5. Meshed Glenohumeral Joint

### 2.6 Testing

The model was loaded according to the in vivo force mechanics discussed in 2.2. The back of the seat and the base of the seat were treated as fixed. An image of the loaded model is displayed in figure 6. The FE model was then solved using the IDEAS_nx 12 FEA software which generated no clear errors in the model or corrupt elements. Corrupt elements are the main contributor to incorrect results in FEA and in a complex shape like the proximal humerus it is particularly important that element checks are performed.

### 3. RESULTS:

The results generated by the IDEAS_nx 12 software are presented in vector components as displayed in figure 7. This information is also displayed in figure 8 which shows the displaced humeral head in the light grey area.

Figure 7. Displacement Results for FE test rig.
Bracing Shoulder Injuries caused by Rear impacts.

4. VALIDATION OF MODEL

This model will be validated in two ways, firstly by model comparison and secondarily by a mechanical test rig. In a paper by Bryce et al [9] a validation of a scapula model was attempted. Using very similar methods of model generation, a model from CT scans was generated. All results were within 3mm accuracy from the original sample. They concluded that “clinically accurate 3D images can be created from CT scans” [9] and that “the results from this work verify that accurate and reliable 3D models can be created from in situ scapulae” [9]. A mechanical test rig is currently being designed which will recreate the moments and forces encountered during this form of rear impact to fully validate the results.

5. TEST RIG DESIGN

The mechanical test rig must meet certain criteria based upon current test rigs and empirical data to accurately reproduce the in-vivo mechanics of the glenohumeral joint. The test rig must accurately recreate the loadings generated during the rear impact crash scenario applying the relevant loadings representative of the in vivo physiological characteristics of the Glenohumeral joint. The test rig must also simulate the torsional loading / deforming forces applied to the proximal humerus generated when bracing to recreate the dynamic muscular stabilization of the shoulder girdle along the line of action of each of the muscles. The test rig that is to be built is a modular, dynamic design allowing for the testing of multiple activities of daily living and directly applied stresses on the glenohumeral joint and potentially other joint in the body. Figure 9 shows a basic structure for the test rig, an explanation of the different part functions is displayed below.
Mechanical Test Rig Design Breakdown.

<table>

<th>Module</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>The disk is a slim lined rotating table, mounted on the side of the test rig. It allows for accurate and strong rotation of the glenoid support column.</td>
<td>The glenoid support column supports the glenoid holder. This column also allows for angular adjustment of the glenoid holder. This enables the glenoid holder to face any direction. The column locks to form a solid support when testing.</td>
<td>The glenoid holder supports an accurate molding of the glenoid which is removable for use in testing. The holder also has an array of attachments to which much of the key musculature around the glenohumeral joint can be attached during testing.</td>
<td>The Proximal Humerus mount simply supports and locks in a model of the proximal humerus for use in testing. Like the glenoid holder it also supports attachments to support musculature and uniquely for the rear impact test it supports a small chair back model.</td>
<td>The Module is interchangeable with each test. Each module has a different purpose for example to re-created the action of an activity of daily living of the direct, blunt impact force of a fall. In the test for the rear impact injury a pneumatic cylinder is firmly mounted to the base of the test rig. This cylinder is computer controlled to recreated the force and acceleration of the impact.</td>
</tr>
</tbody>
</table>

During the testing of the rear impact crash while in the braced position the model will recreate the moment forces from the impact, it will aim to recreate the tensed state of the muscles and the effects of the support back. The forces are to be recreated using a computer controlled pneumatic cylinder module. The musculature is to comprise of thin steel cables surrounded by a dense polymer cover tensed between the relevant test rig fixture and the muscle insertion point. Muscle tension will be measured using torque wrench when tensioning the cables. The seat back is simply a Glass filled Nylon block covered in a 1mm layer of 100% polyester fabric. This is aimed to look at the forces the seat back has on the displacement and forces in the shoulder and so is merely representative of a seat back. As discussed in 2.3 exact seat model properties are not required for this test. In order to ensure reliable, accurate results the mechanical test rig will be validated against 3D motion, loading and deformation data from previous literature.

6. Discussion:

It was the aim of this investigation to try to identify the cause of pain generated in the shoulder complex during reverse impact road accidents.

This is a previously unexplored injury and hence we hypothesized that when braced the shoulder centre becomes posteriorly and proximally located so that during distal impact, large forces are forced on the supraspinatus and subscapularis tendons. The rationale for this hypothesis is that the combination of the biceps, triceps and deltoid restricting forward joint motion and the glenoid restricting backward motion of the proximal humerus the head of the humerus to become posteriorly and proximally located under the forces generated in a automotive rear impact.

A similar study was performed by Scarlat et al. looking at the effect of lateral impaction to the shoulder. FEA was used with retrospective case studies and discovered that when “associated lesions” are considered better outcomes are generated. The follow up conducted however only took place 6 months after trauma indicating that possibly the muscular crushing indicated in this paper was not considered or diagnosed though one patient had developed AC arthrosis [14].

To prove the concept of the crushing injury a finite element analysis was carried out restricting motion using the glenoid and the surrounding muscles and balancing the shoulder with a rotor cuff constant 15N force [13]. The Model displayed a maximum 1.73E-1mm proximal and 2.25E-1mm posterior displacement of the humeral head shown in figure 3.1. Though these results prove the hypothesis it is debatable whether such a displacement is significant enough to crush the supraspinatus and subscapularis tendons.

The model is limited by the fact that trabecular bone has not been accounted for in this study. This was chosen to make the model possible to solve using the current FEA package. Future studies should look at the effects of
Bracing Shoulder Injuries caused by Rear impacts.

...trabecular bone on the movement of the proximal humerus. The model also only includes the glenoid rather than the whole scapula, this resulted in the ignoring of any transferred stress into the scapula and its surrounding muscles. As discussed in 2.2 it has been suggested that the scapula can be considered fixed when muscles are tensed when anticipating a strong impact [14]. This omission is unlikely to affect our results in this light.

The complex musculature around the proximal humerus made the accurate application of force difficult to balance the joint. The use of an evenly deployed rotor cuff load simplified the model greatly and is generally accepted practice [13].

The ability to directly and accurately import the CT images is key to this project. The import of CT data produced a very accurate model of both the proximal humerus and the glenoid. FE models of this accuracy and quality are comparatively new to the bio-mechanics field because until recently the import of data of this format has been lacking in accuracy and ease of use. The ability to easily import CT data to CAD packages has dramatically impacted the bio-mechanics field making it possible to quickly render CT and MRI data for testing. The IDEAS software was also key to the success of the FE model as its high processing power allowed for very fine element sizes across the complex shape.

The model is a very accurate representation of the in-vivo forces generated during an impact of this type and further work on the model should allow for an expansion into an accurate, dynamic shoulder model. The model should also begin to account for associated injuries from lateral impaction forces which depend on the direction of the initial force, the magnitude of the force and on the compliance of the soft tissue at the point of impact [18].

The mechanical test rig when built will form a platform to validate the FE model under any load or motion. The simple design reduces the possibilities for user error and allows it to be a widely usable tool. The test rig is a portable size meaning that it will be possible to use it not just for research but for the teaching of medical and bio-mechanical students.

6. CONCLUSION:

As a result of the study the crushing injury proposed has been shown to be a real possibility. Given that such a high percentage of crashes in the UK are rear impact [1] it is important that it is properly diagnosed. This study recommends that the injury should be checked for in Accident and Emergency when patients come in having been in an accident of this type and complain of shoulder pain. Early diagnosis and treatment will avoid complications later in life. The mechanical test rig will provide further detail and validation of this injury. Due to the complex nature of the injury and the easy confusion with referred neck pain future clinical investigation will be required to define the mechanism of injury and to confirm that the neck is not responsible for referred pain. It is important to define this injury as it is likely to become more common as shoulder and neck surgeons no longer – or rarely – deal with both areas [19].

It has been shown that the anatomical lesions generated following a rear impact may be misdiagnosed [18]. This study recommends that all rear impact patients should be asked about shoulder pain and that any pain should be investigated.

ACKNOWLEDGEMENTS:

The authors wish to acknowledge Prof R J Minns, for the images of the braced position and Mr. A Rangan, for the clinical support he has offered. We are also indebted to Mr. P L Frank for details for the injury and the clinical observations he has offered. We also wish to thank the Laboratory of Human Anatomy and Embryology, University of Brussels (ULB), Belgium for the image datasets used in this experiment.

Inventory System Improvement in ERP Implementation Projects

Michael Boyce*, Dr. Nasreddin Dhafr & Robert Lee
Teesside Manufacturing Centre (TMC)
University of Teesside
Middlesbrough, TS1 3BA, UK

ABSTRACT

Inventory control is one of the most vital areas to manage within a manufacturing company. Implementing an ERP (Enterprise Resource Planning) system gives the organisation the ideal opportunity to further explore and improve this area encompassing stores, purchasing and manufacturing departments.

Some manufacturing organisations nowadays implement ERP and link it to lean manufacturing concepts like JIT (Just In Time), Kanban system and 5S.

The objective of this paper is to investigate how some lean concepts were utilised to assist the implementation of the ERP in the early stages. This was done in a large, multi-national manufacturing organisation. The organisation supplies the oil and gas industry in a niche market.

This work involves the improvements that were made in the warehouse. The main part of this work was done in the Tool Crib. This is a part of the warehouse where all the tools and consumables are stored. These are items that are used in the production process but are not part of the end product. Over the years more and more items have been stored in this area, until now when there is over 5000 items. The work includes the investigation of the rationale for keeping, or not, these parts as well as data collection. The aim been to reduce the inventory by disposing of obsolete items and improve efficiency of the warehouse as a result. The aim of the data collection was to gather data relevant to each of the items. This encompasses a wide range of data stretching from usage history to vendors and their corresponding part numbers.

The work was done and many challenges were met on the way most of these were overcome whilst some are ongoing. This was to be expected as usually in the case of ERP implementation it is very rare to accomplish immediate improvements in all areas.

1. INTRODUCTION AND PROJECT BACKGROUND

Worldwide business competitiveness and the increased speed of information generalisation mean that the integration of enterprise resources and information is necessary for enterprises to survive. Thus, enterprises are exploring the possibilities of integrating their sales, manufacturing, inventory, financial accounting, and human resources into a single managing system [1]. ERP systems assist organisations to integrate and automate these areas [2]. One of the main aims of ERP implementation is not only to integrate the existing business processes into the ERP system, but also to improve them and then implement. As just implementation of an ERP system is no guarantee of optimisation of the company functions. The ERP implementation must be combined with a re-design and re-organisation of the existing processes [3]. Early thinking on Lean often dismissed ERP and other information systems as inconsequential or even inappropriate in a Lean focused company [4]. More recently, as ERP systems have developed, ERP vendors are now claiming it is possible to combine lean principles with the implementation of an ERP system. Bridging the seemingly insurmountable gap between enterprise resource planning (ERP) systems and lean manufacturing [5].

This paper will focus on the first phase of ERP implementation that was carried out in a medium sized company, located in the North East of England. The company manufactures technologically advanced flexible piping for the oil and gas industry and has expanded at a significant rate over the last several years. It was

* Corresponding Author: Tel.: +44 (191) 2959000; Fax: +44 (191) 2959001; E-mail: m.boyce@tees.ac.uk
realised that as the company expanded the need for more efficient Information Technology systems and department integration was essential to maintain progress.

After further investigation of ERP systems it became apparent that outside consultancy help was required who had extensive experience in this area. To this end TMC † (Teesside Manufacturing Centre) was recruited. With their expertise a specific ERP system was chosen which was engineering and project focussed. This was completed by evaluating several ERP systems and then creating a shortlist. The companies on the short list were then invited to demonstrate their wares.

TMC also created detailed process maps of all departments. This was done by conducting interviews with managers and staff from the company. These maps were then analysed and a first phase ERP implementation scoping exercise was carried out. From this it was decided that Engineering, Warehousing, Purchasing and Finance would all be part of the initial implementation drive for first phase. This paper will focus on warehousing and purchasing.

A full review of the methodology that is used by TMC when helping companies with ERP implementation is published in [6].

The scope of this paper will focus on warehousing and purchasing. The biggest issue facing these departments was the organisational culture and the dislike to change.

2. WAREHOUSING

The stores in the company are split into three areas; they are: (1) raw materials, which consists of standard type material, (2) project stock, which is mostly project specific, and includes the end fittings that are of a unique design for each project and (3) the tool crib, which stores all the consumables and tools used in the manufacture of the pipe, these parts do not become part of the pipe.

The first part that was focussed on was the raw material. This consists of a large warehouse with lots of racking holding material such as thick steel wire coils, stainless steel coils and various types of polymers housed in large hoppers. To give an idea of scale, each of the thick steel wire coils weigh nearly 1.5 tonne and each hopper can hold up to 20 tonne of granular polymer. At any one time this part of stores will house in excess of 500 wire coils.

What became immediately apparent was the lack of knowledge of where anything was. There was a general rule that the coils of different types of steel were kept in their own area but there was no record of what stock came in last or what type or weight it was. The only way to find out was to go to the material and read the label. This in itself could be problematic as they were stored up to 10 metres high. This problem was only going to get worse as an expansion was going on at the time and the raw material area was to be more than doubled in capacity. It was obvious that something had to be done immediately.

A benefit of the ERP system is that raw materials can be tracked throughout the warehouse, using unique location codes. Here you are able to input unique code numbers and later able to assign stock items to these locations. Using this system it is possible to know where every part is within the warehouse. To do this a unique location code numbering system had to be implemented. This was first done by numbering each of the storage locations in a rack using a combination of letters and numbers. This was done for every rack and then each of the racks was given a unique identification. This is shown in Figure 1 below.

† TMC is based in the School of Science and Technology at the University of Teesside. TMC specialises in enterprise integration and provides local organisations a service in design, manufacturing and business process improvement.
Each rack was then given an identifying letter so people knew, using a rack map, where it was in the warehouse. It was at this early stage that it was decided to give all the parts in the warehouse a new part number. It was decided to have raw material part numbers start with a “R”, project specific stock to start with a “P” and tool crib stock to start with a “T”. In this way the first identifying letter for each rack was given the same letter to identify which part of the warehouse it belonged to.

Once it was determined what number each location was to be given labels were printed out to stick on the racks. These locations were inputted into the ERP system and so it was possible to print these out through the new system. Doing this meant we could also have a bar code on the label which could become beneficial later.

**RAW MATERIAL**: Before the first phase implementation of the ERP it would take over an hour to book a raw material into stock. Whenever any material arrived two excel spreadsheets and a database first had to be updated. The database would hold information of what was expected to arrive and so this had to be updated. There was then a booking schedule spreadsheet that also had to be updated. There was then the stock control spreadsheet to be updated to keep a record of what was in the inventory. The old process is shown in Figure 2 below.

In addition to these tasks other labels and documentation had to be produced to help identify the material at a later date and also so that the Quality Control department knew what had arrived. This was called the quality
control package and included labelling up the new material. Each batch and type of material in the delivery had to have an individual hand written form filled out. Also hand written tags had to be filled out and stuck onto the material. The delivery note also had to be matched with the purchase order which part of had to be filled in. This process is shown in Figure 3.

![Figure 3: Old style quality control package](image)

To summarise both these processes had to be done for any raw material that was delivered to site. This could mean 50 pallets of material could be delivered at any one time and it was estimated that an equivalent of two stores man were going through the process of receiving raw material 24 hours a day. This was seen as a good opportunity for the ERP system to make large benefits. After the first phase go-live the process for receiving raw material was made much simpler as shown in Figure 4.

![Figure 4: Receiving material after Go-Live](image)

As can be seen, no longer did two spreadsheets and a database have to be maintained. Everything was all in one system. In addition to this benefit it was also possible to know in advance what was to be delivered and when. This helped to manage resources.

Using the ERP system to do the quality control package was even more beneficial than for receiving raw materials. It is now possible to print out an arrival report to match with the delivery note and then to print out as many labels as that is required in seconds, before they had to be hand written. On these labels all the relevant details, including bar codes, were included. The new process for producing the quality control package is shown in Figure 5.

![Figure 5: Quality control package after Go-Live](image)

**PROJECT STOCK:** The project specific stock is stored in its own part of the warehouse but it still had the same shortcomings as the raw materials. The unique location number was also included in this area. In some ways it was more important that it was because of the way the stock was held. The project stock is a mixture of unique and standard items. They are purchased for specific pipes and stored on the same pallet for that pipe. A problem that has occurred in the past would be if an operator could not find all the parts that he required for a specific job then he would take them from another pallet, and so another project. This problem would then snowball, as the same problem would then occur when the parts from the other pallet were required. Using the new ERP system everything is in its own location and to use a part it must be issued from that location. In fact the ERP implementation highlighted this problem and so now there are stricter rules on personnel access to the stores area.
A large problem did occur in this area after the first phase Go-Live. This was that each of these project parts was ordered for an exact pipe, even though usually they are identical if used on the same project. This was done because it is paramount that it is known exactly what pipe a specific part is fitted to for material traceability and so they all have a serial number. If a pipe was moved into the area to fit the project specific parts to and then it was found that it was the wrong one for the part it would get fitted anyway, and so loses material traceability. This issue is covered in more detail in another paper reference. [7]

**CONSUMABLES:** The tool crib is an area that holds the tools and consumables that are used in the manufacture of the pipe but do not become part of the finished product. At the start of the first phase there were just over 5000 separate types of item held in this area and this number was increasing by approximately 30 per month. A small amount of investigation was carried out to determine what items were actually held there, as no one seemed to know. It became apparent that some items had been held in the tool crib for 10 years and never used. It was decided to do a “data cleanse” in the area to capture information on all the parts and then to come up with a list of items to recommend to the company to dispose of. It was deemed that this would also help to determine a finalised list of the items that were required in the new ERP system.

The aims of doing the data cleanse in the tool crib were not only to compile a list of inventory items for the new system but to also help the area to work more efficiently.

The anticipated benefits were:

- To minimise the number of inventory items.
- To minimise the space used.
- To increase the stock efficiency.
- To increase the accessibility of the items.

As the area was examined in greater detail it was found that the parts were controlled in two separate ways. Some were controlled using a database, which had been installed by an external supplier. This gave the supplier access to look at the current stock levels and so re-supply as required. This meant that they were the main supplier of all the tool crib items. Any items that they didn’t stock as standard were still supplied through them and so were charged at a premium. It became clear that the company thought all items were supplied by this company but in reality only a small percentage were ever supplied to the tool crib, as the others were never used. When an item was used it was booked out of the database and so the stock count was kept accurate.

The items that weren’t held on the database were controlled using a card system. A card was held in the storage area and as an item was used the card quantity was adjusted. Written on the card were the minimum and maximum quantity levels. When the quantity level reached the minimum then the card was removed from the storage location and put on a desk at the front of the tool crib. These cards were then given to the buyer for them to order more stock. If an item was required that wasn’t in the tool crib then a purchase request would be produced. This item would then be ordered without any further questions asked. This could be anyone creating this supply request and so there was no control over it.

All the items were split into 40+ groups. These groups were determined by where they were used in the manufacturing process. The problem that became apparent with this approach was that it was found that the same item could exist several times as it would be categorised in several groups because it was used on different parts of the shop floor.

A location numbering system already existed in the tool crib but was not exhaustive and as the years had passed had become a little haphazard as further items were added to the inventory. It was decided to use the same method as what was used in the rest of the warehouse.

Before the data gathering exercise was started it had to be decided what information would be retrieved. A lot of the information on the database and card system was not very accurate and so it was decided to physically examine each item. This meant that manufacturing data could be collected, not just the supplier, and would help the purchasing department look for more competitive vendors in the future.
The information gathered was as follows:

- Lead-time
- R.O.Q. (Re-Order Quantity)
- Last used
- Control mechanism (card system / database / nothing)
- Location
- Our part number
- Manufacturer
- Manufacturer part number
- Vendor
- Vendor part number
- Price breaks
- Description
- Min / max levels
- Cycle time
- Category
- Price / unit

After this information was gathered it was found that over 3000 items had not been used for over one year and of these, over 1000 items had never actually ever been used. They were put into stock when the machinery was first installed on the shop floor and were items that the manufacturers had recommended that the company keep as spares. Even though these items had not been used for a long time it was still felt that it should be the department who may have to use them one day to be the ones to recommend disposal. To this end a list was sent to maintenance.

Adjustments to the descriptions of the items had to be done before it was migrated into the ERP system. This was because of the limitations in the description field. It was limited to 35 characters. The old systems weren’t limited in this way and so additional miscellaneous data had been added to the descriptions. It was thought at the time that this additional data could be used in a part of the new system called “characteristics”. The idea was that the item would be given a very basic description with all additional information in characteristics.

The next step was to decide on the basic description. The maintenance and stores departments did this together as there had always been a disagreement as to what each item was called. As this information was fed back it was used to populate the spreadsheet that had been created to gather all the tool crib data.

As part of the tool crib there is a KanBan area, which is sealed off from the rest of the tool crib. This has in excess of 200 containers. The maintenance and manufacturing departments have access to this area but not to the rest of the tool crib. Before the ERP system implementation the quantity level in this area had to be manually examined each day to make sure they didn’t run out. After first phase Go-Live this was handled the same as the other areas, with a minimum level. When this level is reached they are re-stocked by the rest of the stock in the tool crib. This is an improvement, as they all don’t need to be checked each day, only the ones that are highlighted by the ERP system.

3. PURCHASING

This department is responsible for the timely delivery of raw materials, project stock and tool crib items as demanded by the production plan. This department is split into two areas. These are procurement and project procurement. Project procurement is obviously concerned with the ordering of project specific items. More information on this area can be found in paper. [7]

The general procurement department is concerned with the ordering of raw material and consumables in the tool crib. The raw material part was quite easy to implement in first phase as there isn’t a great deal of variety to
the material and there are only a few suppliers. The biggest change here was that purchase requests and orders are now done electronically. When a part is delivered it can be matched to a purchase order on the system.

4. IMPROVEMENTS IN THE FIRST PHASE OF ERP IMPLEMENTATION

Many improvements have been made since the first phase Go-Live but it has been quite difficult to assign resources as the implementation of the second phase marches on. However some have been made.

In the tool crib it was found a lot of space was taken up by one small item. Most of the storage areas were of the same size and it didn’t depend on the size of the item. Where possible when the new location numbers were set up if the item was small then more than one location would exist on one shelf and so save a lot of space.

Using the new ERP system it became possible to look at the usage of the parts. The most frequently used items were then moved to locations that were nearer the issue area.

After the tool crib data gathering exercise was complete it became possible to create a list of items that were never used. This list was given to the maintenance department for them to examine. Even though some items had never been used in 10 years they still insisted in keeping some of them because they were classed as critical items because if ever they were required then production would stop and so cost a lot of money. Despite this a few hundred parts were disposed of as they were found to be obsolete. This would not have been possible without the data gathering exercise. More information regarding 5S can be found at [8]

It is now possible to have the ERP system create a purchase request when the minimum level for the item is reached. This minimum level is calculated on the quantity that is used on a daily basis, cycle time, and the lead-time to re-furnish the stock. If calculated correctly and efficiently this will be JIT.

Though this isn’t a true JIT system it is still reducing inventory. A true system is a pull system and reduces inventory, finished goods, work in progress and raw material. [9] More information on cycle time and lead-time can be found at [10].

It is possible, using the ERP system, to calculate safety stock, make a demand forecast and determine a re-order point for each item based on the demand history [11].

For the first phase tablet computers had been purchased to aid the use of the ERP system in the warehouse areas. Due to training issues and some teething problems with the wireless networks they were not used after the first phase implementation. Subsequently stores personnel had to go back to the office to interrogate the system. After approximately a month when people had got used to the new system a further push to train and demonstrate the system on the tablet computers was made. Initially this was met with stiff resistance from the stores personnel but as senior management consistently pushed this it was eventually successful. Receiving, issuing and stock take of inventory can now be done without entering the office and so a large time saving is made.

An extra function of the tablet computers is that they have a barcode reader built in. Each storage location and item label has a barcode on it. This saves a lot of time when inputting this information into the system as they can now be read using the reader. This was the main selling point to the stores personnel when training them to use the tablet computers as the tablets are smaller than standard and don’t have a full size keyboard.

A problem highlighted earlier in this paper regarding the way the project stock was ordered to a specific pipe to maintain traceability has now been rectified. Instead of ordering it for the exact pipe, it is now ordered to the project. The serial number of the pipe isn’t noted until it has actually been fitted to the pipe and so creates much more flexibility.

Now that procurement has a lot more visibility in the new system they have started an exercise to find and rate new vendors. They no longer want only one supplier for an item and so are now looking at several for each. It is now possible in the new system to create several suppliers for each item, each with differing prices and lead times.
5. IMPROVEMENT IN ERP IMPLEMENTATION KNOWLEDGE

There are some lessons that were learnt during the first phase. Some of these lessons are:

- **MAPPING**: It was decided for second phase to map the processes, rather than the departments, as it became obvious that processes affecting more than one department caused some of the problems in the first phase. The mapping for the second phase became much more thorough doing this.

- **COMMUNICATION**: It was found that it is very important to update the whole team and the departments affected by the ERP implementation, with the plans, issues and progress of the ERP project. In second phase this is now a priority as in first phase it was found that a lot of data was gathered, especially in the tool crib, that wasn’t used. It may get used in the future but time was very tight to make the Go-Live date.

  It was also found that to keep the organisation updated generally on the ERP project was beneficial as it helped to combat negativity. A monthly newsletter is now produced for the second phase.

- **TRAINING**: The timing and quantity of training should not be underestimated. When personnel are not using the system on a daily basis then it is easily forgotten. In the first phase training was done at an early stage but this didn’t seem to be beneficial as most of it was forgotten.

  In the second phase an IT literacy survey has already taken place to assess the present knowledge of IT systems and so help with the plan for training.

6. CONCLUSION

A lot of improvements have actually been driven by the ERP implementation and would probably not have occurred, or discovered, if it wasn’t for it. It certainly wouldn’t have happened so soon.

The second phase is now well under way and includes the implementation of the Planning, Commercial and Manufacturing departments as well as full implementation of Engineering and Finance. Engineering had an interim solution for first phase and so integration will be improved in second phase.

A lot of lessons were learnt in the first phase, some have been highlighted, and it has changed the way that the second phase is been implemented and it also helps that the ERP team have a good idea of what to expect and what problems can occur.

Embedding ERP in an Engineering Projects Environment

Robert Lee*, Michael Boyce, Dr. Ahmed Abbas and Dr. Nasreddin Dhafr

ABSTRACT

Software solutions such as Enterprise Resource Planning (ERP) systems are contributing greatly to growth, efficiency and effectiveness of the business by providing end-to-end best practices. ERP system implementation in organisations requires understanding of strategic, tactical and operational levels of the business to embed best practice improvements. Hence, embedding industry best practices as an end-to-end solution is a common avenue within modern day manufacturing organisations to increase competitiveness. This paper focuses on the challenges involved in embedding an ERP system and associated processes within an engineering projects organisation. Changing market conditions, economic pressures and business improvement needs are explored to understand the strategic requirements for investing in large ERP implementation projects. However, consideration should also be made to the failure rates and impact on the host company in pursuit of this strategic change. This study puts forward observations during a phased implementation of an ERP system within such a bespoke manufacturing environment. Lessons learnt particularly in Projects and Engineering Department illustrate the challenges faced during the first phase in the ERP lifecycle encompassing the all important ‘Go Live’ date and post ‘Go Live’ activities.

Adaptation of the ERP system to the business requires using tailored tools and techniques such as process mapping, Business Process Re-engineering (BPR) and configuration management were employed to facilitate the improvement process. The tailored tools contributed to better visibility, acceleration of the implementation and improved traceability of parts, with more clear roles and responsibilities. Over and above this, the work also addressed challenges such as user acceptance, training, time constraints, resources, software limitation and communications with different functional areas. The activity undertaken specifically in the Projects and Engineering Department addressed issues with regard to standardisation, data integration, quality of data, reporting mechanisms and traceability. After overcoming the difficulties encountered in these areas, lessons learnt were created and stored as a knowledge base to enhance performance for the forthcoming phases of the implementation and minimise barriers on host companies while moving from a traditional company towards the ideal of a totally integrated enterprise.

1. INTRODUCTION AND BACKGROUND

Organisations are constantly looking for ways to gain a competitive advantage over their competitors. It is a core business necessity to remain competitive that is motivating and driving organisations to re-evaluate how they operate commercially. In recent years the world has seen the rapid improvement of information and communication technologies (ICTs) and the growing importance of Enterprise Resource Planning (ERP) systems as a critical resource.

This paper starts by reviewing historical events that led to the growth of Enterprise Systems, specifically focusing on the influence from business process re-engineering (BPR) in 90s and how this led to a surge of ERP becoming an enabler to initiate change. Furthermore the paper will comment on literature concerning the integration of ERP systems and implications on procedural and cultural issues across organisations. Using evidence from previous case studies we explore different views and perspectives, highlighting the important facts when implementing an ERP system. This is followed by a case study carried out at a small to medium sized company based in the UK.

* Corresponding author: Tel.:+44 (0)1912 959 621; E-mail: Robert.Lee@wellstream.com
The company specialises in bespoke manufacturing of equipment used in the oil and gas sector. The authors will follow the company as it embarked on an ERP implementation project from pre-implementation activities to Go-Live and beyond. This study concludes by addressing the challenges and lessons learnt from this case study as a result of integrating ERP in an Engineering Project Environment.

**BUSINESS PROCESS RE-ENGINEERING (BPR):** One technique that assisted organisations to transform how they worked in order to add value to the customer and dramatically cut costs was BPR. This section will briefly summarise the growth of BPR starting first with the business process perspective. A business process perspective simplifies complex tasks by splitting the entire procedure into smaller processes or steps. Process improvement and simplification is gained by examining each process or step to incrementally identify and eliminate bottlenecks and non-value events. [1]

In contrast to the improvements by increments, an alternative was offered suggesting it was;” better to throw a broken process away altogether and start from scratch than to improve it incrementally.” [2] This approach focused on radical re-design of processes which ushered in the new era for BPR.

Business process re-engineering (BPR) became infamous by the following statement. "Forget all you know...Don't automate, obliterate.” [3] This endorsed the view that any non-value adding processes would be “obliterated” instead of automating them using IT systems. BPR sole focus on value adding processes ultimately became its demise as it failed to take account of people factors. Evidence was seen of this in 1995 as “Pacific Bell announced that it was cutting 10,000 employees because of ‘reengineering’.”[4]

**ENTERPRISE SYSTEMS:** After the collapse of BPR, not surprisingly organisations wanted to consolidate their lost BPR activities. Considered by some to be the replacement, an Enterprise system was a commercial off the shelf package that was described as “the seamless integration of all the information flowing through a company”. [5]

Enterprise systems were originally designed for automating repetitive tasks. The emphasis of such systems was to establish a standard input, process and output to computerise the process in order to provide enhanced services and more functionality. By embedding generic business processes that were based on best practice and integrating them into all functional areas, enterprise systems looked like an ideal solution. However, “even though the promise of ERP is to offer a moldable configuration based on business requirements, current technology still inflicts a separate structure.” [6]

A report from a case study supported this claim and found the enterprise system forced inflexibility “with features that were at odds with its own requirements.” [7] Another case study noted that by standardising practices involved un-needed disruptions to many silos of activities.” [8] The main outcome of many implementations was the,” proliferation of failures in implementation and growing dissatisfaction.” [9]

Our research indicated, “the notion of ‘best practice’ can only ever mean the dominant perspective.” [8] In other words, process was no match for politics and the influential members of the board who exerted their power to change adopted practices. In this example, it is shown the importance for gaining the trust of people with power and status.

The Totally Integrated Enterprise (TIE) framework concurs with this view by stating, “Commitment and sign on is required from all functional units, else bottlenecks will occur.” [10] TIE’s emphasis is based on drawing together the ERP system, organisational functions and people with the aim of bringing deep rooted, and long term change through the process improvement activity.

**PROJECT ENVIRONMENT:** Due to the changes in customer requirements, many ERP vendors had to cater for demand from the growing project-based market. Within a project-based or engineer to order (ETO) environment organisations had the situation where products were designed, engineered and customised in pre-production to match each customer’s order. [11] As a consequence, maintaining a detailed list of all variations to the process became heavily taxing.

With the background set we have gained knowledge of the changes in the business environment that promoted the growth of enterprise systems and are presented with the following facts:

- Organisations have been reengineering their business process in order to achieve a competitive advantage since the early 90’s
- Enterprise systems are integrated solutions offering best practice. Although different scholars have reported Enterprise systems may constrain enterprising behaviour.
- Enterprise systems have moved to encompass ETO environments, and;
• TIE is a framework that brings together all aspects of the ERP systems and is used as a way to instill improvement.

2. CASE STUDY

Although implementations of Enterprise Systems have been documented within large organisations research is still in the initial stages for small to medium sized enterprises. This study was used to gain an understanding of an ERP implementation in a medium sized company attempting to embed ERP in an Engineering Project Environment. The company operates in a niche market where they design and manufacture bespoke products for the oil and gas sector. The host company appreciated that this was a huge undertaking which prompted them to seek professional consultancy and knowledge transfer from Teesside Manufacturing Centre (TMC) †. Before the ERP vendor selection stage The TMC used multiple tools and techniques including TIE concepts discussed earlier as the way of identifying improvements to make.

To understand an organisation in the context of this paper we will briefly introduce the organisational tiers, functional silos and the project environment. An organisation is a complex network of management tiers and information silos. An organisation can be categorised into three distinct levels. The strategic level, the tactical level and the operational level shown below (see, Figure 1).

![Organisational Tiers](image)

Figure 1: Organisational Tiers [12]

The strategic level includes the decision making activities with a long term view of the company’s future; these strategic activities can be further broken down into tactical activities. The tactical level which is comprised of medium term planning activities aims to achieve goals set about from the strategic level. The last level is the operational level which consists of day to day shop floor activities. The advantage using this approach is that it provides a structured way of thinking about information to be collected for management of an effective enterprise system. An organisation is also made up of a number of smaller self-governing functional silos. Organisations are often localised into different functional areas such as Engineering, Finance, Stores and Purchasing. (see, Figure 2).

† TMC is based in the School of Science and Technology at the University of Teesside. TMC specialises in areas including business process improvements, lean manufacturing, computer aided engineering and ERP implementations in small to medium sized enterprises.
This case study results from participant observation throughout a phased implementation of an ERP System and focuses on Engineering and Purchasing. A phased approach meant the implementation was completed in stages. Each phase of the implementation would develop a solution for one or more functional areas that would be integrated into the enterprise system before progressing onto the next phase. The breakdown of the phases was as follows:-

Phase 1. Purchasing, Stores, Finance and Engineering (partial).
Phase 2. Engineering, Manufacturing, Human resources, Quality, Sales, Document Management and Planning
Phase 3. Maintenance

All activities of the implementation of the enterprise System were governed by a Steering Group. The steering group consisted of the executives and senior managers from the company, consultants from the ERP vendor and TMC. The steering group was in charge of the strategic management of the project, and its first task was to form an ERP project team (see, Figure 3).

This consisted of a project manager and personnel from key functional areas including Stores, Engineering, Finance and finally two representatives from Purchasing. Consultants from the ERP vendor and the TMC were
booked to offer specialised advice when needed. Two high caliber graduates who were on the UK government supported Knowledge Transfer Partnership scheme (KTP Associates) were employed to provide additional support in the implementation. Having the assembled the project team, the following sections will discuss the process of embedding the Enterprise System.

**Embedding Enterprise Systems:** Enterprise Systems are implemented using three essential types of knowledge to embed them. The strategic management thinking is captured from staff at the organisation; best practice is captured from the consultants and best usage of the software from the ERP vendors. This trinity of knowledge needed to be balanced to achieve harmony in processes. Managing this balance can become complex and it was necessary that the project team aligned the business processes with their organisational tiers and functional silos. This meant that during the implementation period, the project team had to ensure that all function silos were not working in isolation. This made it possible to collaborate and standardise processes between function silos offering best practice across the supply chain.

**Enterprise Systems and Re-engineering Processes:** During the design stage stakeholders had to make another significant decision: should they try to re-engineer their processes before implementing ERP, or should they implement the ERP system first without undertaking thorough reengineering of their current processes? Option 1 was to commit time to reengineer processes before a major implementation, Option 2 was to integrate ERP whilst at the same time manage the business change process, or Option 3, which is to implement without changing the processes. Without streamlined processes the implementation would be encumbered with illogical and often non-repeatable processes. A decision was made to proceed with Option 2 whereby the integration and process change would be performed together.

In partnership with TMC, the company commenced mapping sessions to illustrate all staff duties at every organisational tier and functional silo. Process maps were created in collaboration with the personnel that had operational and management roles in the activities to capture the process fully. Using these current state process maps the team identified bottlenecks and any non-value adding activities. The team then embarked on a BPR exercise to agree to an ideal state map that facilitated the implementation process by enabling staff and ERP consultants to highlight possible improvement points and eliminate waste in the business process.

To commence putting theory into practice the ERP consultants configured the system ready for the implementation team to start testing. Each ERP team member would train their respective departments after the solution was finalised. It was found that the enterprise system overcame many issues based on standard jobs because it literally fits into an enterprise system designed for tasks such as bulk purchasing and receiving inventory en masse etc… Further evidence of this can be seen in [11] based on the same ERP implementation which shows benefits from a stores perspective.

**Lessons Learnt:** This section focuses on lessons learnt from the ERP system implementation and hopes to provide some valuable insight for companies preparing or in the midst of implementation proceedings. Although the embedding of ERP provided benefits, it was not echoed throughout all functional areas. One department that underwent major changes to totally integrate the organisation was the Engineering department.

Historically the Engineering department benefited from lots of flexibility. For example, in order to procure parts, Engineers would simply populate the relevant cell within a customised excel spreadsheet called the Bill of Materials (BOM). After entering minimal information such as the part description, the detail of the drawing and corresponding notes it was sent to the procurement department to buy.

With the introduction of the ERP system an inflexible process was enforced. For instance, in order to procure a part, engineers needed to acquire a unique part number, use standardised part descriptions and select valid tracking options which were traditionally managed by Quality. Moreover, the BOM spreadsheet which was now output from the Enterprise system created even more tasks for the engineers to perform as the Enterprise system needed to be instructed how parts related to each other to enable Procurement and Stores to buy and receive goods to the correct project.

The role that engineering played in the process had been radically altered and as a consequence produced areas where a greater effort was required to configure parts that would be accepted by the system rather than performing value adding engineering tasks. This raised the legitimate question about how much integration was enough? It was noted that the integration process caused discontent to other silos of activity.
To summarise the benefits of enterprise system provided:

- One single technology platform to share common data across the entire organisation.
- Real time sharing of information.
- Integration of function silos.
- Eliminate entry of duplicate information; and
- Indirectly optimised processes during BPR exercises.

Disadvantages are:

- Difficult to implement due to major changes to business practices.
- Inflexibility of integrated design; and
- Dependency on external consultants; this was an area of increased cost during implementation.

The ‘Go Live date came and passed without any major faults. However, overcoming the concerns noted pre Go Live was of top priority. In order to assess which improvements to take on first the company used a tool called the ease/benefit matrix (see, Figure 4). All concerns were noted and given a corresponding number. They were then rated by consensus from consultants and team members and mapped on the map below.

Figure 4: Ease / Benefit Matrix

Obviously solutions providing the most benefit and easy to implement took top priority while solutions that were hard to implement and offered lower benefits were given a lower priority. Members of the steering group and the project champion were actively involved in this stage to lend support where needed. Phase 2 of the implementation plan is currently underway whilst continuous improvements activities are implemented in parallel.

3. Conclusion

In a tough economic climate it is the authors’ view that Enterprise systems play an increasingly important part on the sustainability of businesses to perform at world class levels. During the work at the case study company there was an expectation of some business change but not at the scale initiated when embedding ERP. In order to
Implement the ERP system in the project-based company, the participants had to customise and configure the system to follow their own bespoke processes.

Customisation of an enterprise system within an ETO environment is much more time consuming and complex when compared to a mainstream implementation. Bespoke processes found only in the ETO/project sector created much frustration. As we saw examples of this in the lessons learnt section where the system forced engineers to prepare overly detailed BOMs thus making a fairly simple task in creating an engineering part turn out to be a complex chore. That is the limitation of ERP systems at the moment. The whole aim of ERP systems is to find the optimum solution – which is fine for volume manufacturing but not so good for project-based environments. While this and other technical issues will be addressed, the author does not envision this being available without modifications.

Nonetheless, there was evidence of the company benefiting from ERP systems when receiving bulk parts in. As standard parts could be created en masse and only needed to be configured once in the system. The main reason for this was that enterprise systems work most easily when configured to fit with volume or batch jobs. Although ERP systems have become increasingly powerful there is still no one-size-fits-all solution to cover all the differences between companies that are volume-based and project-based. Unfortunately, this means chances are higher of encountering problems with customisation of processes or software limitations in an ETO environment.

However, technologies will continue to develop and ERP systems will become more pervasive in the project environment. Future research will conclude with the next phase of the implementation and should provide quantifiable results to analyse the success of the ERP implementation so far. The recommendation by this paper is for organisations to work together as a whole and connect its people, processes and technologies by doing so will aid in developing an optimum solution for all.

ABSTRACT

Process management tools and techniques applied to manufacturing process environments are essential for enterprise continuous improvement. Recent research have studied methodologies and made recommendations for application of the process management to manufacturing, information or administrative processes. The ITIL library is an example of very sophisticated solution for information technology service management (IT). It documents industry best practice guidance focusing on providing high quality services, while placing special emphasis on customer relationship in the use of IT services. However, there is no evidence in the literature of a suitable process management tool for diagnostic purposes in the system / process life cycle. There is, therefore, a need to design a generic methodology framework for process diagnostics management. The aim of this paper, therefore, is to develop a methodology framework for diagnostics applications in manufacturing processes management. The methodology used for system design were developed based on detailed diagnostics processes analyses and personal interview of researchers and industry practitioners. The diagnostics framework contains steps leading to process management implementation and techniques for planning, execution and evaluation of the diagnostics processes. The framework integrated the ITIL library principles. The ITIL is structured to address problem and incident management for service support, and describes procedures which can classify data as incidents and problems. The framework is designed for quick and easy decision-making.

1. INTRODUCTION

Manufacturing and service enterprises use diagnostics systems for preventive and maintenance management. The main purpose is to test products during manufacture processes and also to monitor the production system. The diagnostics system is an important tool for management set correction and improvement of processes. Diagnostics management covers planning, realization, execution and improvement of diagnostics processes. The objective of diagnostics process management is to achieve as well as guarantee quality assurance.

Recent research and application have methodologies and recommendations for application of the process management in manufacturing, information, maintenance and administrative processes. The ITIL library is an example of sophisticated solution for information technology service management (IT) and documents industry best practice guidance focusing on providing high quality services, while placing special emphasis on customer relationship in the use of IT services. However, there is no evidence in the literature of a suitable process management tool for diagnostic purposes in the product / process life cycle. There is, therefore, a need to design a generic methodology framework for process diagnostics management.

2. THEORETICAL FRAMEWORK AND LITERATURE REVIEW

ISO 9000 for quality management and ISO/IEC 17025 which is the standard for management and technical procedures refer to the requirements for quality management system implementation and certification. These standards can be used for management system establishment in diagnostics management. ISO/IEC 17025 is focused on the operation and effectiveness of the quality management system within the laboratory, and its technical requirements to address the competence of staff, methodology and test/calibration equipment. Laboratories use ISO/IEC 17025 to implement a quality system aimed at improving their ability to consistently produce valid results. It is also the basis for award of accreditation. Since the standard is about competence, accreditation is simply a formal recognition of a demonstration of that competence. ITIL (Information Technology Infrastructure Library) is the documentation of best practice for Information Technology Service Management and consists of a series of books giving guidance on the provision of quality IT services, and on the accommodation and environmental facilities needed to support IT [1] - [4].

ITIL has been developed in recognition of organizations' growing dependency on IT and embodies best practices for Information Technology Service Management. The problem and incident management is part of service support management. The goal of Incident Management is to restore normal service operation as quickly as possible and minimise the adverse impact of incidents on business operations, thus ensuring that the best possible level of service quality and availability is maintained. “Normal service operation” is defined here as service operation within Service Level Agreement (SLA) limits. Incident Management must be as quick as possible. An incident is defined any event which is not part of the standard operation of a service and which causes, or may cause an interruption to, or a reduction in, the quality of the service.

The main goals of Problem management are: to minimize the adverse impact of incidents and problems on the business; to prevent recurrence of incidents related to these errors. The problem management process requires the accurate and comprehensive recording of incidents in order to identify effectively and efficiently the cause of the incident trends. The main advantage of ITIL application is the complexity and depth of solution and ITIL books cover following management areas: security management, software asset management, financial planning, strategic management etc. The solution which is included in the ITIL standard is based on “best practice” recommendation.

The disadvantages are presented. Sometimes ITIL is used by manufacturing managers who do not understand this standard, because ITIL describes processes and management process for informatics system but not for manufacturing systems. Manufacturing managers understand only the quality management standards of ISO 9000. Also definition of scope application and translation ITIL requirements for manufacturing can be a problematic.

Although ISO and ITIL standards are support business process management application the relationship between ITIL and BPM has described suggests support ITIL with process-oriented tools such as workflow management systems by Branner [4]. It discusses the need for workflow management support of service management processes to achieve service level compliance, and presents criteria for determining which IT Service Management processes can and should be supported by workflow management systems. The IT Service Management processes defined by ITIL are evaluated and divided into four basic process classes according to their suitability for workflow management, thereby laying a foundation to future top-down approaches for comprehensive ITIL tool support.

2.1. BUSINESS PROCESS MANAGEMENT

One way to achieve process performance management system establishment is by successful implementation of business processes. Management of business processes is an approach used in many industrial applications [1]- [12].

A high number of citations for example a Google.com search on „Business Process Management“ returns more than fourteen thousand pages where this phrase appears. The science on Business Process management BPM issue is the subject of research focused on methodological or technological solution of BPM problems [1]. The main problems of applications BPM are described by Wasana Bandara in article [5], where fourteen global experts were interviewed. The outcome form this study describes the lack of governance, standards, methodology, tool support for process visualisation etc in the implementation of BPM.

3. METHODOLOGY DESIGN

Designed methodology concept helps to implement the diagnostics process management system based on ITIL application. The concept has been developed into two steps:

1. Analysis of diagnostics processes and current needs of responsible managers, staffs, researchers and technicians in diagnostics area. The designed questionnaires were used in this step. We have obtained process attributes of diagnostics processes.

2. Study, selection and modification of suitable methods and tools for business process management and performance measurement.

3.2. METHODOLOGY FRAMEWORK

Methodology framework is presented by Table 1. As we can see the table presents key steps and activities in defined order. The methodology concept is based on business process and process performance management theory and the implementation of ITIL. It means application of BPM and PPM in first step. This step leads to:

- process analysis and key process indicators setup
- process description, modeling and optimization,
- system of evaluation and process execution

The second step ITIL application helps to mark the outputs of diagnostic process as incidents or problems e.g. ITIL describes reference processes for support of decision making. The outputs from this process can be data or information about diagnosed object (diagnosis). Implementation of information infrastructure namely knowledge databases for incidents and problems help to reduce the time for decision making and information analysis.

The information infrastructure can also be built on Service Oriented Architecture (SOA) which provides methods for systems development and integration where systems group functionality around business processes and package these as interoperable services. SOA also describes IT infrastructure which allows different applications to exchange
data with one another as they participate in business processes. Service-orientation aims at a loose coupling of services with operating systems, programming languages and other technologies which underlie applications [10].

3.3. CASE STUDY

The case study presents the designed methodology framework application for diagnostics of soldering in electronics production process. The soldering process is an important part in electronics assembly. The aim of diagnostics process is to ensure quality control of soldering material and components. This kind of process is an example in off-line diagnostics which is used before soldering process starts for process setup or in case of breaking production due to unacceptable failures in process. It is releasing to determine what happened and why in a short time. Due to this fact the diagnostics process has to be standardized and described. The practical application of designed methodology presents how this process is described and managed.

The methodology implementation is now described as follows.

3.3.1. STRATEGY DEFINITION AND KEY-INDICATORS SET-UP

The aim of this step is to define key process indicators based on performance metrics definition. In this case the analysis of current situation has been done from discussion with specialists from the diagnostics area. The specialists identified these current problems:

- diagnostics processes aren’t described,
- processes aren’t monitoring and executed,
- information and knowledge aren’t shared,
- system for diagnostics process management doesn’t exist.

These problems are analyzed by applied process management system according to the designed methodology. Firstly the strategic goals and key process indicators were formulated. The main strategic goals were formulated in four perspectives of Balanced Scorecard. The key process indicators have been developed for process execution and process performance measurement. The key performance indicator types can be divided into 3 groups:

- time-related key performance indicators (e.g. throughput times, processing times, frequencies),
- cost-related key performance indicators (e.g. process costs/rates on the basis of the performance standard) and
- quality-related key performance indicators (e.g. number of processors, error rates, deadline reliability).

3.3.2. PROCESS ANALYSIS AND MAPPING

The diagnostics process of soldering was strongly analyzed in this step. The aim was identification and description of all processes attributes and activities during this process. Process mapping means description of all processes attributes and relationships between them. The result of process analysis is demonstrated in Table 3.

3.3.3. PROCESS MODELING

We decided used ARIS methodology was used for process modeling. This methodology is based on oriented object modeling languages. ARIS allows describing reality from another point of view. The main model - model of added value as presented in Figure 1 is one example. It is basic view on process structure and relationship for top managers. The three kinds of processes can be seen in this model. They are control (planning, marketing), main and support (quality management, accounting, service) processes. The model can be decomposed as a detailed process entitled eEPC (Extended Event-driven Process Chain) process model in ARIS. Figure 2 presents example of a test soldering model. The key attributes of this process are recorded in this model.

Figure 1: Generic Diagnostics Process Added Value Model
In this step the ITIL Problem and Incident Management was applied. The aim of this application is definition key process for problem and incident solving. Figure 3 shows the process model of knowledge database formation. In this model we can see the main input to database. It is Incident and Problem report (outputs of previous and incident management processes). Figure 4 presents the main event and process in incident management. The start is rise of incident on diagnostic process. The incident has to be delivered to Internal Customer Contacts Diagnostics support. Detected incident has to be recorded to Incident Report. The data from report are compared in knowledge database and the incident is marked like a new incident. In case of known incident the data in database can be updated. Next processes described in Figure 4 are started on based of the result of detection process.

Figure 2: Model of soldering diagnostics

3.3.4. PROBLEM AND INCIDENT MANAGEMENT IMPLEMENTATION

In this step the ITIL Problem and Incident Management was applied. The aim of this application is definition key process for problem and incident solving. Figure 3 shows the process model of knowledge database formation. In this model we can see the main input to database. It is Incident and Problem report (outputs of previous and incident management processes). Figure 4 presents the main event and process in incident management. The start is rise of incident on diagnostic process. The incident has to be delivered to Internal Customer Contacts Diagnostics support. Detected incident has to be recorded to Incident Report. The data from report are compared in knowledge database and the incident is marked like a new incident. In case of known incident the data in database can be updated. Next processes described in Figure 4 are started on based of the result of detection process.

Figure 3: Process model of knowledge database formation
The report contains the description of problem or incident identification. The reports contain predefined and compulsory form item. The database provides in information platform and these records are stored in the knowledge database supported by IT platform as part of enterprise information system. The output of the knowledge database can be a model of causes and events. Service team can use this result for support for decision-making about incident and problem solving.

3.3.5. Process Measurement and System for Key Process Indicators Execution and Evaluation

The last step is implementation of system from process performance management. In this case the system is based on process control application. Processes control involve measuring efficiency of the business processes implemented in IT systems and putting control systems in place that will monitor compliance with range of legal regulatory requirements. It means building of information architecture, system and implementing software tool. This solution corresponds with the new trend in process management.

Companies that are able to align their processes to the requirements of their environment and surroundings will not only gain a competitive advantage, but they will also be able to manipulate this alignment better and faster than their competitors. The prerequisites for this solution are the supply of decision-relevant information and an ability to transform this information quickly and effectively into sustained measures for targeted alignment of business processes. We decided to use the ARIS Process Performance Manager (ARIS PPM) software tool for process control in this case, because this tool can be implemented to any information system and structure. Owing to the fact that we are using tools ARIS for process modelling and optimization of processes, we decided to use the software ARIS PPM.

First experience of ARIS PPM implementation has shown benefits of this solution in the manufacturing area for technological process control, in this case for diagnostic process management. The SW tool ARIS PPM helps to make analysis and processes monitoring, particularly:

- real process course,
process time,
- comparing of the real and planned key indicators value,
- type and kind of order.

The results of process mining and analysis have been used for process models correction and KPI planning. The responsible management obtains quick management and performance view.

4. CONCLUSION

Diagnostics processes, information and knowledge represent important values for a company these days. These process attributes should be controlled if the business process management is implemented. This paper presents design of methodology for diagnostics process management and shows one way to manage information and knowledge in ITIL. ITIL (Information Technology Infrastructure Library) has been described in previous and the example of the application was given in the case study.

The case study focused on diagnostics in the manufacturing area. The results of the study present a model of the soldering process and short application of ITIL. The example of description implementation of the ITIL for diagnostic of the soldering process was also shown. The results can be used in information systems implementation and provide a sophisticated base for responsible management and decision-making. The first experience of implementation indicates that designed solution helps to reduce of process time and control of process quality.

A complex analysis of designed methodology and ITIL application for diagnostics process management would be one possible direction for further work.

Abstract

For several years the domestic markets of manufacturing organisations have started to reach maturity [1] and companies have sought to expand their international operations in order to grow. This has meant there has been an increasing emphasis on the debate on whether companies should remain global or localise their marketing mix, and to what extent each element should be adapted or standardised. International marketing can be defined as ‘the performance of business activities designed to plan, price, promote and direct the flow of a company’s goods and services to consumers or users in more than one nation for a profit’[2]. In this paper the authors argue against the statement ‘manufacturing organisations are either mindlessly global or hopelessly local’ and demonstrate that manufacturing organisations can successfully combine a global and local approach if they carefully choose the elements that they adapt or standardise.

1. Definitions of Adaptation and Standardisation

The process of “globalization,” refers to the big-picture process that draws products, services, and markets around the world closer together. It is a process that involves a complex array of actors and institutions, including firms, governments, NGOs, and consumers. This process is typically analyzed at the macroeconomic level, where the country is the unit of analysis.

While academic and social debates about ‘globalization’ ‘global village’ etc continues, corporations are expected to create profitable businesses and generate returns for investors by entering trans-border markets, compete against international rivals, risk investments, find and develop opportunities in a turbulent world which is in continuous competitive transformation. Their power of leadership and foresight needs to manage extended international enterprises, enter diverse international markets, and manage risks and uncertainties that range from global supply chains to financial risks to geopolitical risks.

Production is increasingly a global activity. In this ongoing internationalization of production, multinational corporations (MNCs) have played a critical role. While most multinationals still originate from advanced, developed nations, there is a growing number of MNCs from countries that do not belong to this select group.

There is a range of international activities that takes place within the framework of the multinational corporation and these activities can be analyzed from a number of different points of view.

Globalizing therefore refers to the process by which a given firm begins a journey of becoming global in its vision and corporate objectives in order to achieve competitiveness. Few, if any, firms have completed this journey ‘truly global’; many, however, are globalizing. Globalizing is a process that unfolds not at the level of the country but at the level of the firm, and consists of the actions firms have to take as they become more engaged in that process.

An approach that is prevalent in a large part of the MNC literature takes the internalization decision as given and focuses primarily, and in more detail, on the division of labor between parent and affiliate within
the MN C. MNCs th at relocate activitie s internationally o rganize p roduction both in sco pe (the set of products) and in depth (stages of production) between the parent and the affiliate in such a way as to take advantage of international differences in factor abundance and factor prices [3], [4] and [5]. Interestingly enough, the theory of the multinational corporation as initially developed is primarily conceived from the perspective of advanced, developed countries [6], [7]. These theories primarily view the MNCs as a vehicle to relocate labor-intensive activities to affiliates in low-wage countries. They rationalize on one-way MNC activity in which MNCs from the capital-abundant North set up affiliates in the labor-abundant South [8], [9].

To understand the process of globalizing, we certainly can not ignore the broader process of globalization. Our global political and economic systems create the context for our business enterprises. As corporations with affiliates abroad, MN Cs al most by de finition hav e a vertical component. A M NC’s affiliates abroad need firm-specific (intangible) assets such as headquarter services, R&D, patents etc. to operate and these will be traded within the firm. Since this latter vertical component is part of any MNC, Markusen and Maskus [10] do not make it the distinguishing characteristic between, what have been called, vertical and horizontal integration models of the MNCs. Essential for the vertical models in their view are differences in factor intensities of the components of the production process and relocating these to take advantage of factor price differences.

The MNCs from these countries have affiliates in both more and less advanced countries. On the one hand, the liberalizations in China, Malaysia, Thailand or Vietnam account for the boom of affiliates from MNCs with parents in these middle-income countries.

There is no all-encompassing theory of the multinational corporation. There are a variety of models that focus on different aspects of multinational activity that all have some empirical relevance. MNCs take advantage of factor prices and have them break up production accord ingly. On the other hand, other researchers argue that breaking up production to take advantage of factor cost differences need not be an essential motivation for MNCs [11], [12], [13]. Access to rich markets is key and to save transportatio n costs, MNCs may set up shops in other developed count ries instead of hav ing to sup ply these markets through exports, even without factor price differences. Finally, there is the view that MNCs emerge in an effort to jump tariffs or other existing costs associated with trading goods [14].

The degree to which manufacturing organisations are and should be either globally or locally orientated and therefore the adaptation and standardisation debate is by no means a new subject of discussion, with increased attention from the late 1960s. Buzzell [15] was one of the first academics to address the concerns facing companies wishing to operate on a national scale. He argued that standardisation has the potential to be a useful approach, but there are barriers to this. In this way multinational standardisation implies the same product, the same price, the same distribution systems with the same promotional techniques and message in every country that the firm wishes to operate in [15]. This would relate to the idea of ‘global’ above. In contrast a ‘local’ marketing strategy would be one in which no elements of the marketing mix are the same in any one national context. The interesting and relevant point to make about this piece of research is that at it s disavantages both it s and disavantages to s standardisation and therefore adopting a global approach. However it fails to examine exactly which elements of a marketing mix should be adopted. We can now examine in further detail the standardisation side of the debate.

2. THE STANDARDISATION ARGUMENT

Levitt [16] argued that there is no need to adapt any elements of the marketing mix to suit local tastes due to the ‘globalisation of f markets’. Therefore he would argue that manufacturing organisations can be global in their marketing approach without being ‘hopeless’ in fact that a global approach is in deed a successful one. Levitt [16] can be identified as the principal advocate of the standardisation viewpoint. He argued that the world is becoming more homogeneous with technology being the driving force behind it. A firm that was in accordance to this viewpoint would standardise all elements of its marketing mix.

There are numerous advantages for a firm choosing to adopt a standardised approach. One such advantage is that standardisation allows a brand to build up a strong global presence that is easily identifiable [17], and thus consistency with customers. A second advantage is the ability to take advantage of economies of scale [18], which in turn leads to significant cost savings, particularly through product design. One early example of this is Henry Ford’s Model T where he stated that you could have ‘any colour
so long as it’s black’ [19]. Thirdly a standardised approach can improve planning and control and finally standardisation allows a company to exploit good ideas that are formed in one context and extend these to other contexts [18]. However evidence within the business context heavily suggests that there are very few manufacturing organisations if any that can be identified as taking a completely standardised approach.

There are also disadvantages to adopting a largely standardised strategy. Firstly a standardised strategy is primarily product driven and fails to take into account the needs of consumers [20]. This could lead to disastrous results if the needs are very different from the benefits that a product supplies. For example Chee and Harris [18] state that consumer tastes and preferences are very specific and vary considerably. Furthermore if the products are not adapted and therefore remain at the same cost to produce, the price of the products could be so that they do not match what is affordable in a given country or more expensive than local competitors.

Furthermore there are many cases in the business context of companies who have tried to introduce their brand to international markets, without adapting. One such example is Hallmark. Hallmark are known in the U.K for their greeting cards with sentimental messages within, so that the British customer does not have to write their own message. However when Hallmark tried to introduce their brand to the French market they did not adapt their product apart from translating the messages into French. The French prefer to write their own messages in greeting cards and therefore the Hallmark brand failed in France [21].

3. THE ADAPTATION ARGUMENT

The polar opposite of standardisation is adaptation. Advocates of this viewpoint highlight that there are important differences between countries in terms of culture, stages of economic and marketing development, political and legal systems and customer values and lifestyles [2]. This would imply that adaptation is the appropriate approach. Kacker [22] distinguishes between compulsory (legal) modifications and voluntary modification. He claims that marketers can increase the probability of success by being aware of and responding to different cultural realities. We can thus infer that adaptation has the benefits of responding to customer demand in each cultural setting. Douglas and Wind [20] state matter of factly that arguing that a strategy of universal standardisation should be applied ‘appears naive and oversimplified.

However in recent times there has been an increasing tendency to adapt some elements of the marketing mix and standardise others. Simon-Miller [23] states that the only global brands are McDonalds, Kodak and Coca Cola. However the authors would suggest that even Coca Cola adapts to local tastes and changes product names accordingly. For example in France what is termed Diet Coke in the U.K has been renamed Coke light in France to meet legal requirements and country specific expectations. Diet Coke would imply to this culture that instead of having reduced sugar content the drink would aid weight loss. Additionally McDonalds at one point was seen as a true global brand. However it adapts to local market conditions and customer market needs. For example in France McDonalds expands its product offering to include Beer and yoghurts. It is evident that different companies adapt or standardise to different extents. There are many authors who have attempted to identify to what extent elements of the marketing mix should be standardised. The EPRG Paradigm examines this process through examining management orientations.

4. THE EPRG PARADIGM

One such approach is examining management orientations through the EPRG paradigm. According to Keegan [24] the way that a company responds to global market opportunities is dependant upon the way the management sees and understands the nature of the world. This ‘worldview’ is explained through the EPRG Paradigm. The first orientation that management can adopt is the ethnocentric orientation, which is also termed the market extension approach. This is defined as assuming that the home country or domestic market is ‘superior’ compared to the rest of the world. In this way companies who see the world in this manner assume that products and practices that are successful in the home country will succeed anywhere in the world without adaptation. This is type of strategy may lead to economies of scale and lower costs, however as a result sometimes opportunities outside of the home country are ignored and the company fails to understand the local culture.
By contrast the polycentric orientation can be defined as the ‘belief or assumption that each country in which a company operates is unique’ [24]. It can also be termed the multidomestic approach. Companies adopting this approach identify the differences in each national market and treat each one as unique. In this manner large scale adaptation occurs. This approach has the advantage of being able to understand the local culture and adapt accordingly. However it is costly and if adaptation is carried out on a large scale the company can lose brand identity and a consistent brand image across each of its markets.

A Regiocentric approach is one in which product uniformity is sought within a cluster of markets [24]. The cluster can be organised in a variety of ways including geographic proximity, language or membership of a regional union. A company adopting this type of approach benefits from economies of production and marketing. However if the chosen market cluster is too large it could slow down the ‘diffusion’ of the product. One example is if the company decides that its market cluster is going to be the European Union. The European Union is expanding constantly and now encompasses a large variety of cultures within it.

Finally a geocentric approach is one in which the company views the world as a single market [18]. Within this approach there is a high level of centralisation and coordination of activities which in turn leads to lower research and development costs, rationalised product lines, economies of scale and worldwide distribution of the product. However this strategy is largely dependent on careful and continuous market research. This however is not the same as an ethnocentric approach; it is instead a combination of an ethnocentric approach and a polycentric approach in that it is a global strategy that is highly responsive to local demands. Companies that adopt this type of approach are often termed transnational companies, with Unilever being an example of success.

The different orientations are summarised below. Arrows numbered X represent advantages and arrows numbered Y represent disadvantages.

Lower Costs

Figure 1: Adapted from Howard Perlmutter [25]. The addition of the arrows are authors own contribution.

Following one of these paradigm approaches determines to a certain extent the level that a company chooses to adapt or standardise its marketing mix to each international market. It demonstrates to some level that manufacturing organisations are not necessarily ‘mindlessly global’ or ‘hopelessly local’ and in
fact that some companies adopt a strategy that is somewhere in the middle of this spectrum. Nevertheless an ethnocentric approach might be portrayed as ‘mindlessly global.’ The framework is a clear and useful tool for examining an enterprise’s view of adaptation and standardisation, but it is not prescriptive and once these orientations are evident within a particular company they maybe hard to change. In fact Perlmutter [25] stated that even if a firm wishes to have a geocentric orientation there are both obstacles and drivers to developing this orientation such as the distrust of big international manufacturing organisations by political leaders in host countries. This would be a significant obstacle to a geocentric orientation. The framework looks at the organisation and its management as a whole rather than looking at each element of the marketing strategy. However the EPRG paradigm is not the only approach in existence. Many authors have sought to provide an integrated standardisation framework.

5. FRAMEWORK FOR STANDARDISATION

What is perhaps interesting and advantageous compared to the previous approach is that Jain [26] distinguishes between marketing program and marketing process. Program refers to the different elements of the marketing mix and process refers to ‘tools that aid in program development and implementation’. According to Jain, the degree of program standardisation or adaptation depends on five individual factors. The first of these factors is the target market.

5.1. TARGET MARKET

According to Jain, the decision on whether to standardise or not is situation-specific, which is evidently a different way of examining the issue than the EPRG paradigm. Target market encompasses both the geographic area and economic factors. For example, economic factors influence the level of development of a country and it can be argued that companies with their home base in a more developed country moving to a country with a similar level of development are more likely to standardise than those from a similar domestic market moving to a country with lower economic development. Indeed, when Chandra, Griffith and Ryans [27] attempted to adapt Jain’s framework to transferring advertising from the USA to India, they found that similarity between the target markets of the USA and India would be associated with more program standardisation. Chandra, Griffith and Ryans state that as a partial result of the similarity between the American and Indian markets manufacturing organisations have been successful in standardising their advertising programs.

5.2. MARKET POSITION

The second important factor to consider according to Jain [26] is that of market position, which in turn encompasses market development, market conditions, and competitive factors. If a product’s foreign market is at a different stage of development than that of its domestic market, it is likely to need to adapt to match this gap. The three conditions that affect the degree of standardisation or adaptation that is required are cultural differences, economic differences, and differences in customer perceptions. There are many examples of companies who have failed to take account of cultural differences. One such example is Kellogg’s whose cereal brands include Corn Flakes and Rice Krispies. In the 1990s, after increased pressure for competitors and stagnant U.K. and USA markets, the company decided to expand its operations to India. The decision was based on the low pressure competitive environment and the size of the population. In 1994, after international barriers to trade in India had been taken down, Kellogg’s decided to enter the market. However, due to cultural differences, the concept of eating breakfast cereal in India was new and novel. Kellogg’s not only had to market their own brands and product lines but also the concept of eating cereal. This proved to be unsuccessful as the Indian consumers treated Kellogg’s products as a one-off purchase. However, from an other perspective, it was an extent to meet cultural differences can damage the brand identity [21]. According to Holt, Quelch and Taylor [28] one of the three factors that affected consumers’ purchasing decisions with regards to global brands is ‘global myth’. According to this piece of research, consumers see global brands as symbols of ‘cultural ideals’ and see them as a way of creating ‘an imagined global identity that they share with like-minded people.’

5.3. NATURE OF THE PRODUCT
The third element which is considered to be important in determining the level of standardisation is the nature of the product, which encompasses the type of product and product positioning. Indeed Boddewyn, Soehl and Picard [29] found that the degree of standardisation that is feasible depends on whether the goods are con sumer non-durables, con sumer dura bles o r i ndustrial goo ds. St andardisation for con sumer non-durable goods such as foods standardisation would be most difficult as a result of differences in national tastes. This is perhaps interesting as there are a variety of examples of food brands that have attempted to use standardisation across national borders such as Mars for example. In the case of consumer durables such as washi ng machines or ca meras standardisation can be at an advanced level, with only slight adaptations made to meet leg al require ments. However it is pre dicated th at the most a dvanced standardisation will occur with industrial products. Additionally it is thought that if a brand or product is positioned in the same way in all overseas markets standardisation is feasible to a large extent.

5.4. ENVIRONMENT

The fourth important element is the en vironment. This is sig nificant as it consid ers fac tors from a n external perspective. This element includes physical, legal, political and marketing infrastructure factors. This piece of research supports the seminal article by Buzzell [15]. According to Buzzell different countries have different legal require ments with product design, advertising, competitive positioning, pricing and employment. We can see evi dence for example of the different restraints on advertising throughout the world. In Kuwait only 32 minutes of advertising are allowed per day, advertising to children is banned in Sweden, alcohol advertising is banned in certain countries as is tobacco advertising [2]. So me of the most significant political constraints are tariff and other trade barriers, local content or export require ments and the existence of cartels. According to Jain [26] the marketing infrastructure ‘consists of the institutions and functions nece ssary to create , develop and service demand.’ Buzzell [15] states that the differences and availability of certain types of media and or distribution channels can affect the degree of standardisation. Perhaps the most relevant concern with media today is that of the internet, which has become a powerful source of advertising within the USA and the UK. In the USA there are 501 internet users per 1000 people where as in China for example there are only 11 internet users per 1000 people [2]. So we can see here that at the legal level compulsory adaptations are needed, but the core marketing can be kept the same and voluntary adaptation might be necessary with relation to media reach limitations.

5.5. ORGANISATION FACTORS

Organisation fac tors en compass corporate o rientation, headquarters-subsidiary r elationships and del egation of auth ority. Cor porate orientation addresses the issues o f the EPRG par adigm that were analysed earlier. As we can see this corporate or management orientation forms only a small part of Jain’s standardisation framework and in that way this framework is more comprehensive. The importance of the headquarters-subsidiary relationship and the delegation of authority coincide.

6. SUMMARY

Product standardisation was very popular in the 1980s, but since then the focus has shifted to adapting at least some elements of the marketing mix. It appears that standardisation arguments are built on a series of assumptions about consumers that are not necessarily always accurate. There are various frameworks that exist to determine the level of adaptation that is necessary by a company wishing to market its products in international markets. From this research and examples of companies that have been both successful and failed dramatically when entering into new markets it appears that the most appropriate response is to maintain a core product and add peripheral modifications. The advantage of this is that the company can keep a consistent global brand image for example like Coca Cola or McDonalds that has a good reputation and a certain personal ity and co notations at tached to it, however it can adapt according to legal requirements and customer preferences like tastes in every culture that it operates in. The strategy that is adopted should depend on the product and the target market. Evidently no such strategy is guaranteed success.

Potential of Benchmarking

Munir Ahmad*

School of Science and Technology
University of Teesside
Middlesbrough, TS1 3BA, UK

ABSTRACT

This paper describes how to measure and benchmark manufacturing performance as a first step on the journey to performance and competitiveness improvement. Based on the research and experience we have simplified the benchmarking process and have developed a methodology which can be easily applied by an organisation in order to identify the potential benefits and hidden plant. It has been quite common to determine in companies during the first benchmarking exercise that; the hidden plant may well be in access of 30% of output, stocks may be reduced by 50%, the fixed cost can be reduced by anything up to 20%, potential variable cost reduction by a further 10% and customer service is poor. These potential benefits identified through benchmarking provide interesting opportunities, given that they may often be achieved with minimal to zero capital expenditure, and are delivered through the people of the organisation itself. The measurement framework of benchmarking a process is covered based upon three elements; measuring the output of the process which is the performance, measuring the input practices that are applied to deliver these outputs and measuring the culture and softer issues that ensure that the practices are applied and outputs are delivered. This paper provides a methodology which has been applied to various manufacturing companies but does not offer a prescribed template for benchmarking and scoring performance. While it provides the framework, measures and industry world class targets, the actual detailed framework and scoring must be determined by the individual company. A set of data and case studies are also presented to help the organisations understand how to interpret the mass of information generated in a benchmarking study and focus on priorities to start the improvement process.

INTRODUCTION

Manufacturers are required to provide their products to their customers at the expected time, with reasonable prices, and meeting the required quality [1]. Benchmarking is a performance improvement tool and usually used to improve process effectiveness, product quality and service delivery. It enables an organisation to compare existing performance to others, and identify elements that can be adopted in their business context. The result is often a business case for making changes in order to make improvements. Benchmarking is widely used, and there are many different approaches; ranging from models of quality measurement to basic comparison undertaken on a pragmatic basis. It is often necessary to tailor an approach that provides a sustainable method of benchmarking in view of the organisational goals and business needs. There are four types of benchmarking [2]:

- **Internal benchmarking**: this type of benchmarking applies more to large organisations that have various business units. It is about comparing internal operations from one sister company to another.

- **Competitive benchmarking**: this specifically compares competitor to competitor, using the product or function of interest. This goes beyond the traditional product or service engineering, but it is important to learn and understand about competitors’ methods, their processes, innovation, strategies, markets, etc.

- **Functional benchmarking**: this is the comparison of similar functions within the same broad industry, using wide industry leaders as partners.

- **Generic benchmarking**: this involves establishing the comparison of business functions or processes that are the same, regardless of type of industry. Generic benchmarking is a long-term challenge and reflects a total change in the culture. It is usually found in learning organisations.

The benchmarking often uses a number of key performance indicators (KPIs) for comparisons of performance. The KPI is a number, or value, which can be compared against an internal or external target ‘performance benchmark’, to give an indication of performance. That value can relate to data collected or calculated from any process or activity [3], [4]. The KPIs are often classified as; ‘strategic-in-nature’ KPIs, or ‘operational-in-nature’ KPIs. Operational KPIs are used by managers to plan and control programs at operational level, while strategic KPIs provide guidance to both managers and policymakers who have to make decisions from a more global perspective. Generally, KPIs should be selected according to how they relate to the

*Contact details: Tel.: (1642) 342443; Fax: (1642) 342401; E-mail: m.m.ahmad@tees.ac.uk
strategic aims of the organisation and how they can support the corporate-level performance indicators. This means that KPIs, whether they are operational or strategic in nature, must tie in to strategy.

The first task for the persons undertaking the benchmarking is to use their experience and mature judgment of improvement processes, plus their knowledge of the plant, to determine what is practically achievable in the future and what the priorities are for that particular plant. For example, while the hidden plant may represent the largest financial opportunity, the plant operates in a low cost restricted market so the focus will be to reduce the costs.

**THE PROCESS PLANT’S BENCHMARKING METHODOLOGY**

The methodology of benchmarking the process plants as shown in Figure 1 was developed [5] to assist in the performance improvement of the process plants. The manufacturing performance assessment introduced by this methodology is presented in Table 2.

---

**Figure 1: Methodology of benchmarking the process plants**

In this methodology the authors have presented a framework on how to measure and benchmark the performance of the process manufacturing plants. They have defined the following measures for use in benchmarking the process plants:

1. **Customer services**
   - On Time In Full (OTIF)
   - Customer complaints.
   - Due date reliability.
   - Adherence to production plan
   - Stock turn.

2. **Reliable assets**
   - Product rate
   - Quality rate
   - Availability

3. **Operational excellence**
   - Statistical process control
Potential of Benchmarking

- Manufacturing velocity

4. Motivated people
- Absenteeism
- Training days
- Staff turn over

5. Safety, health and environment
- Annual reportable injury accidents
- Environmental performance

The sequence of these KPIs, however, gives a complete set of strategic performance measurements, related to different strategic dimensions. The appropriate combination of measures is determined by the nature of the actual industry. A bulk chemical industry, for example, may focus more on the adherence to sales and operational planning (S&OP), whereas a consumer product industry is encouraged by its final customers to pay particular attention to issues such as OTIF and customer complaints. In general, these KPIs support the corporate performance indicators at the corporate level of the organisation, such as ‘return on investment’, ‘return on assets’, ‘market share’, ‘customer loyalty’, ‘stakeholders satisfaction’, and so on. It was also recommended [5] to use fewer focused measures to make the process more effective. As a guideline it was advised that the total number of measures should be less than 15.

The benchmarking targets are decided and made available once the type of benchmarking has been agreed upon [5]. It was stated [6] that many companies have a problem when performing benchmarking activities. This problem is caused by a difficulty in retrieving quantitative data relevant to world-class or competitors’ performances. It was also highlighted [6] that there is little work being done to address this problem or, at least, to propose a dynamic technique that can help manufacturing organisations in this area. When data for benchmarking are not available, the organisation is advised to establish targets the best way it can [6]. Organisations have always set performance targets and used measurement systems to track the achievement of targets [7], [8], [9], [10]. There are four methods that can be used to set or generate performance targets [7], [8]. They are as follows:

- **Historical targets:** this method is often used, owing to its simplicity in implementation [11]. The best historical performance of an activity would be defined, then used as a performance target.

- **External targets:** by using this method, the world-class performance of best-in-class operations is collected, to use for benchmarking purposes. Table 1 shows some superior performances of process industries’ world-class plants that are often used as performance targets. Importing external benchmarks from competitors’ performances, however, is often an essential requirement for competitiveness in any business.

<tr>
<td>7</td>
<td>Training Days per Employee</td>
<td>12 days</td>
</tr>
<tr>
<td>8</td>
<td>Absenteeism</td>
<td>&lt; 1 %</td>
</tr>
</tbody>
</table>

- **Internal targets:** these targets are based on comparisons of the performance of internal processes. In this method, the performance of the best performing process in the company will be used as a benchmark. This method is myopic, however, in the sense that it looks only within the organisation and may limit the company’s performance relative to its external environment [11].

- **Theoretical targets:** in this method, the targets are determined by the use of theoretical calculations, or by simulation analysis. Setting performance targets on a theoretical basis is exceptionally useful, as it defines the performance capability and limitations of the process. A considerable disadvantage of this method relates to the difficulty and time needed to define it. The theoretical targets of the process would enable effective comparisons of process performance to benchmarks from external sources; they would help in
assessing the capabilities of operations and whether or not they are able to perform similar to best-in-class operations.

Some calculations on how to define performance gaps in the process manufacturing plants can also be used [5]. Some of these calculations are as follows:

Variable cost gap = \((\text{actual variable cost} - \text{world class variable cost}) \times \text{output}\)

Fixed cost gap = \((\text{actual fixed cost} - \text{WC fixed cost})\)

Stock savings gap = \(\left(\frac{1}{\text{Actual stock turn}} - \frac{1}{\text{World class stock turn}}\right) \times \text{Turnover}\)

Hidden Plant = Output \(\times\) \(\left\{\frac{\text{World Class OEE}}{\text{Actual OEE}} - 1\right\}\)

\text{OEE: is the overall equipment effectiveness measure.}

A benchmarking report [12] revealed that the competitiveness of the UK process industries is average when compared with world class levels and that there is a ‘hidden plant’ of 28% of the UK’s current effective capacity. That is, if the UK’s average OEE performance was raised from its current level to the world class levels then the UK process industries’ effective capacity would increase by 28% for minimal capital expenditure. Releasing this ‘hidden plant’ would support additional sales of nearly £10b per annum which increases value to shareholders.

Additionally, a lean manufacturing study [13] highlighted that for most production operations only 5% of activities add value; and 35% are necessary non-value activities; while 60% of activities add no value at all. This study highlighted the fact that the elimination of waste represents a huge potential in terms of manufacturing improvements and the key is to identify both waste and value; develop knowledge management base; and realise that sustainable improvement requires the buy in of the people operating the processes and managing the business, and therefore a culture of continuous improvement.

The relationship between application of best manufacturing practices in manufacturing plants and the ability to achieve superior performance (see, Fig. 2) is usually studied and findings are used to drive improvements.

Fig. 2: Practice - performance relationship
OPERATIONAL PERFORMANCE MEASURES

Operational performance measures are in some cases selected for benchmarking, with respect to their relevance to the operational objectives and the strategic KPIs. Some of the commonly used operational measures are as follows:

- **Manufacturing cycle time**: the total time that the process takes, from start to finish, producing the required production. This time normally comprises of the time required for cleaning, loading, processing, and emptying the equipment.

- **Value of stock in warehouse**: all the money the system invests in purchasing things the system intends to sell.

- **Cost reduction**: KPIs under this category measure the achieved cost reduction through an improvement program.

- **Amount of wasted materials**: material losses from processing, quality control inspections, handling and transfer of materials.

- **Quality measures**: these measures comprise of ‘right-first-time’ performance, defects per unit of production, and detailed pareto diagrams, etc.

- **Equipment uptime**: uptime is defined as the time a process operates at its standard maximum proven rate, while making a defect-free product. The ratio of uptime in the total available time is often calculated as follows:

\[
\text{Uptime} = \frac{\text{Valuable operating time}}{\text{Valuable operating time} + \text{Total losses}}
\]

- **Equipment downtime**: downtime is defined as the period when the equipment is not available to fulfill its intended role. Downtime can consist of planned activities, such as scheduled maintenance, repair and overhaul activities and unplanned activity as a result of a failure, or accidental damage.

- **Resource utilisation**: resource utilisation is defined as the proportion of time that a resource is used.

- **Final product yield**: it’s the percentage of transformed raw materials into salable product.

- **Production capacity**: production capacity is defined as the maximum rate of output that a production unit is able to produce under a given set of operating conditions.

The basis for calculating operational performance measures, however, differs from one sector to another, from plant to plant, or even from one operation to another operation within the same plant. The manufacturing cycle time is an example, as, in some cases, it might be calculated by simple, straightforward equations, or in other cases, may require complicated calculations.

6. **BENCHMARKING IN A CHEMICAL PLANT**

This selected example is a multi-product, multi-purpose batch plant. It operates under a company that is a leader in engineering, production and after sales service in the oil sector in Africa. The demand forecasting activities in this plant are based on judgment and depend on experience. The output of the forecasting process defines the expected sales volume and this output is used to support planning decisions. The management of the company has been concerned for some time about the lack of performance measurement and lack of benchmarks that facilitate the planning decisions. The manufacturing assessment [5] is used to assess performance of the plant. Section 4 of this assessment is shown in Table 2.

The analysis of results revealed that the plant requires an improvement strategy which can take the performance of the plant to the world class levels. The overall performance of the plant scored 24 points (see, Table 3). And according to this performance the plant is in division 3 ‘Below Average’, therefore, according to the performance index attached to the assessment, the plant has scope for improvement. A detailed analysis of the operational and maintenance excellence is required to assess the potential improvements. Through the manufacturing assessment, the plant is at risk with the existing performance of OTIF (on time in full) delivery performance, that is, customers can use new suppliers once they find them. Any supplier has OTIF between 71 and 99.99 % is better than this plant’s performance. The plant also needs to adhere to its production plan by elimination of process variability that causes processes to take longer time, and also reduce downtimes caused by setups, and breakdowns. The plant has low OEE resulting from low product rate which is again resulting from process variability. The company has very poor performance in regard to stock turn; therefore, this measure requires maximisation through reduction of all inventories and increase of sales. The absenteeism and
training are people issues and both have direct impact in productivity and quality of production. The plant has low performance in the measures related to these two issues.

It was also identified that tools such as Kanban, Kaizen, just in time (JIT), statistical process control (SPC), business process reengineering (BPR), total productive maintenance (TPM), single minute exchange of dies (SMED), poke yoke and 5S are some of the most appropriate tools to improve manufacturing performance in this plant. In general, a sustainable performance improvement should be aligned to a firm's ability to continually achieve quality, reduce costs, and deliver products or services to customers in the expected time. However, performance problems can arise from different causes; therefore, there is no unique solution to solve all problems.

</tbody>
</table>

After the analysis of performance, it was concluded that the plant requires some improvements to start at the operational level. The operational effectiveness model (see, Fig. 3) is chosen as a tool for improvement of the plant’s operational performance. The aims were, however, to achieve reduction in the total cycle time of some selected processes, optimise batch sizes, and increase yield of the final product.

The utilisation of manufacturing resources in this plant as in many other plants is a crucial issue. In an ideal manufacturing operation, the processes would operate at full utilisation of all resources. For example; there would be full utilisation of manpower, equipment time, and capacity, there would be zero waste from the handling and processing of raw materials combined with no scrap on the process utilities. However, this situation is rare in real operations. The difference between the ideal and the real situation is due to losses [7], [8].

### Table 3: Performance Index
The plant manufacturing has considerable scope for improvement. The plant requires a detailed operational excellence assessment, with a high likelihood of significant benefits through manufacturing, maintenance, and operational changes.

Division 1: Poor
The plant manufacturing performance has scope for improvement. A detailed analysis of the operational and maintenance excellence is required to assess the potential improvements.

Division 2: Below Average
The plant appears to have manufacturing and maintenance practices which, while average, could be improved. The assessment has highlighted some areas of the plant with further potential.

Division 3: Average
The plant has good manufacturing and maintenance practices and it appears to be exploiting learning opportunities.

Division 4: Good
The site is aware of the scope for further maintenance and manufacturing improvement. The plant is approaching a winning standard and demonstrating leading manufacturing and maintenance practices.

The operational effectiveness model is used to reduce the losses in the plant to the minimum levels. The manufacturing objectives of the plant were defined by informal interviews with some key individuals in the plant. It was concluded from the study that, the minimum production cycle time, maximum yield of final product, and minimum total production costs are the main three objectives of the plant. This was a good input for design of the operational effectiveness model.

There are several benefits of cycle time reduction and some of them are: minimum waste in time, cost reduction, increased flexibility, less time for risk probabilities on hazardous processes, and efficient employees.

The raw materials have the largest portion in the manufacturing costs. When the raw materials are used inefficiently, a waste will be created which will lower sales revenue and create an environmental problem [14].

The economic batch quantity is a best practice to achieve minimum cost of manufacturing. The capacity decisions are vital to the manufacturing plants as they are affecting number of dimensions in the business such as delivery date, product prices, and warehouse requirements. Costs associated with production setups, resource utilisation, and inventory holding are all related to the batch quantity and contributing to total manufacturing costs. The link between stocks and financial performance of organisations is strong [16]. The organizational objective ‘maximizing return on assets’ is a good example of this link. An advantage of manufacturing at economic batch quantity is the tuning of the output of manufacturing to either meet only the market demand, or to produce for demand and for inventory. Therefore, when the manufacturing process optimised for cycle time
to be the least possible time, and yield to be at its maximum potential level; then the economic batch quantity will ensure that the plant will not overproduce to meet the objective of those two factors.

8. CONCLUSION

The methodology used in this paper suggested that there will be a significant opportunity to improve the performance of the majority of the existing assets. Through benchmarking, gaps are identified and an outline of a procedure to quantify existing gaps was provided. All the tools provided by the methodology of benchmarking within the process plants focus on quantifying a financial gap; this sets out the priorities and justifies the case for continuous improvement. After identifying the gaps, guidelines were given for companies on how to introduce process improvements which are realistic and achievable. The paper also has investigated the techniques that used to define a performance targets to assist manufacturing plants in attaining their goals. No one target setting method is enough in itself as the competition may have deployed better equipment, technologies or innovations to generate high performance results. Therefore, it is advisable to use the different target-setting methods in conjunction, as none of these methods are adequate, individually, for determining performance targets. The results of application at the selected case study plant revealed that there are significant losses on time and money. The improvement in the time of the process will lead to an increase in the value of the product, thus creating financial savings.

\textbf{ABSTRACT}

In recent years there has been widespread discussion concerning the shift away from traditional production paradigm and clear advancement of lean manufacturing as a fundamentally new approach. This approach is dominated by product quality, differentiation, and price. The paper argues that the move beyond high performance production is necessary in order to create long term organization competitive advantage. Organizations are entangled in environments where producers, suppliers' customers, and external agencies interact with each other. This interaction stimulates and creates innovation and change in all the participants. Thus an organic environment is required to accommodate both the lean manufacturing and the internal organization sense making. The use of sense making concept as the main tool for organizational learning is pivotal. The paper illustrates how the above have been developed and implemented as an integrated approach to creating an organic lean manufacturing organization in two large manufacturing companies in a developing Country. The approach combines the use of Emergence Strategy approach, Lean manufacturing, sense making, capability enabling, change creation, and problem exploration and solving approaches.

1. INTRODUCTION: PAST AND PRESENT- LEAN-FIT AND NOT LEAN-THIN

One may credit Henri Fayol as a main pillar of modern management and theory with its core assumptions of a high performance organization in the early part of the 20\textsuperscript{th} century. He saw performance achievement in the context of an organization infrastructure that was centralized, functionally specialized and hierarchical, highly defined, in which everything had its specific place. Management was perceived as a champion for planning, organizing, forecasting, coordinating and controlling. Many of the later management researchers followed the same philosophy [1], [2] by proposing new tools for the same framework. Generally our current cost/waste reduction tools or frameworks still focus on improving the implementation of Fayole's view. In reality majority of management authors have provided an extended model of this view, which is still much in use to the present day.

2. ORGANISATIONAL FORMS FOR THE 21\textsuperscript{ST} CENTURY

In the last two decades more innovative views of organization structures started to emerge which valued the integration and synergy of human capability, creativity, and technological advancements. Traditional views that people should be told what is best started to break down. A de-structuring of the over-structured forms emerged in a number of industries [3]. In the face of increasingly competitive environments, the traditional mechanistic focus appears weak and breakable [4].

As organizations entered the concept of global village, they realized that global environments value response, flexibility, choice variations and not, pre-fixed and predefined products. As their customer base changed to a more educated and informed entity the organizations realized that customers can define their needs and expectations. As a reaction to this fundamental change a new paradigm for organisational forms and behaviors started its evolutionary cycle [3]. Organizations aimed that they have moved from efficiency to effectiveness. The lack of definition for effectiveness, and over generalization of this concept,
initiated a huge weakness for the future development of performance management. The wishful thinking for finding a solution to all problems suddenly became a mirage of reality with the introduction of 'Lean production', downsizing, and core capabilities. Organizations which previously had no clear reasons for getting rid of employees or closing down unprofitable divisions, suddenly found a plausible justification. Instead of developing new horizons for organizational and management thinking, they were again pushed down the Foyle 'le' mind-frame. As the global customer base grew and economic wealth increased, organizations faced large demand for their products. Organisations moved their production sites to low-cost countries. The implementation of this move and limitation of educated workforce in those regions meant the further justification of 'new tools and old framework'.

In a parallel cycle some organizations looked to different approaches and were not blind followers of fashionable cues. They moved on a change in design principles that amounted to a major shift which included success factors, innovation, creativity, integration, flexibility, and cross functional synergy [5].

The current global financial crisis seems to be a blessing in that it forces us to rethink our naive prides and over-claimed assumptions. Organizations were all moving so fast to solve all our problems using 'Lean and mean' organizations with guaranteed competitiveness and success. Lean was everything. Suddenly we are faced with the questions such as: why has VW group increased sales while Toyota (lean production initiator) did not. Why did GM, an advocate of LEAN face immense problems. There are no clear evidences that show our Lean organizations did better that the not-so-Lean organizations in the current crisis.

In the post-industrial/information age organizations seem to have followed the same principals of the Taylorism values using new techniques and methodologies. All the techniques and approaches such as business process reengineering, supply chain engineering etc... Push organizations to do better and better, the same old thing.

It seems that they are being brainwashed that the customers require the 'old things' but better and cheaper. The traditional Taylorism view of the company as a centrally-driven entity that creates wealth by getting better and better at doing the same thing is a till persist [6] in our traditional view of a 'lean' production. At the same time new concepts such as lean production, learning, and lean manufacturing are requiring us to think creatively within the context of achieving highly specified targets with minimum wastage and bare requirements. Flexibility and space for change as given in not really focused and assumed customer and producer behavior. The focus has changed from creative human capability building to maximizing the human resource productivity. The inregnation required between strategic management and engineering, and manufacturing paradigms is becoming superficial [7]. Continuous deep innovation is based on the ability to synergistically balance the above domains [a system that specializes in exploitation will discover itself becoming better and better at an increasingly obsolescent technology. A system that specializes in exploration will never realize the advantages of its discoveries] [8].

Competition in the intensive industries is no longer complex; rather, it is in the non-traditional, creativity-intensive industries that we face the real challenges. The future requires value creation by the conversion of 'possibilities' to 'customer desires'. Industries are on the beginning of a 'business des ign' and 'product creation' revolution in our organizations which enriches itself organically, and accepts that seeing future as an investment, must include some additional activities which in the short term is non-value adding activity. In the academic world, this approach was well practised such as industrial placement, consultancy, and research. Sadly enough even the academic world is moving towards the failed approach of the industrial world.

If businesses are to ensure long term competitive survival, they need to enrich Operational effectiveness with 'creativity competence effectiveness' and refine Strategic flexibility, with 'strategic change creation'. In this way we can see that the future successful companies need to focus on excellent exploration capabilities rather than exploitation mechanisms.

The criticality of organisation's structure, size, strategy, technology, environment, culture, and the ir complex and intrinsic relationships have been highlighted a number of researchers. Burns and Stalker [9] propose a fit between structure and the rate of change in its environment must occur if an organisation is to achieve maximum performance. Mintzberg [10] has extensively and passionately researched the importance for organisational structure. Miller [11] has exemplified the important links of strategy and structure. Handy [12], [13] suggests implication of cultural factors in relation to organisational design and structure and the need for new organisational forms. Pascale, Millem and Gioja [14] demonstrate the critical role of design approach and creativity as the life line of the organizations. Mabey, Sala man and...
Moving towards Creating an Organic Lean Manufacturing Organisation

Storey [3] identify the critical relationship between organisational structure and design, and human resource management.

During the 1950s, the Toyota Motor Company, inspired by the waste minimization concepts developed by Henry Ford in the early 1900s introduced advanced manufacturing methods that aimed to optimize the resources it takes for a single product to flow through the entire production process. Toyota engineered an organizational structure focused on the systematic identification and elimination of waste from the production process. James Womack, Daniel Jones, and Daniel Roos introduced the term “lean production” in their 1990 book *The Machine that Changed the World* to describe the manufacturing approach established by the Toyota Production System. In this context any activity that did not directly lead the creation of product was considered as waste.

Lean production typically represents a paradigm shift to reducing time intensity, material intensity, and capital intensity of production for product-aligned “one-piece flow” pull production.

In the concept of traditional LEAN how can corporate loyalty be Value added activity and how can it be related directly to main production activities. The traditional lean approach at most will allow organizations to relate this to their current well defined products (understood customer expectations). This seems to develop a culture in which organizations accept that rather than creating future desires we are addressing current customer expectations. This is a dangerous path to getting better at the old things.

3. AN ENRICHED VIEW OF LEAN FIT (ORGANIC LEAN) APPROACH

If one assumed that organisation performance is related to their ability to manage various kinds of social problems, and to deal with the motivational and emotional problems arising due to negative feedback and failures [15], [16] then we may look for a different integration of Lean Concept. This was indeed the authors approach in the creation a Lean-fit manufacturing capability in a number of companies in a developing world country.

In this approach two main classifications for creating a Lean-Fit organization were identified. A person enriched in both should be resilient and able to handle the commercially and emotionally threatening consequences of failure and success.

1. The first group is called Lean – factors including: lean operational tools and concepts. Tools and concepts in this category included high-performance work systems, high-performance work practices, total quality management, and target management.

2. The second group consists of eleven Organisational Strength factors which represented our focus from work organization and human resource management. These included: Sense-making capability, trust, Corporate loyalty forces, Integrated communication culture, Creativity and creative thinking, Shared experiential learning, Bottom-up Strategic capability and belief, Internal ly created change initiation and management, Shared achievement focus. It is important to note that since products are always changing the organization must replace product loyalty by corporate and customer loyalty.
4. ROLE OF EMOTIONAL INTELLIGENCE, SENSE-MAKING, COMMUNICATION, AND WORKGROUPS

Employees work as a way of developing social and economic status, and enjoy emotional attachments as a way of creating motivational energy, and value their attachment as a sense-making process. Their loyalty is a result of this process which may have no real rational logic or evidence behind it. It does however create surplus energy within the individuals in the company.

Sense-making is a process of continued redrafting of an emerging issue, which is enriched by further data through the process of exploration. The idea that sense-making is driven by plausibility rather than accuracy is in contrast with the assumption that the accuracy of managers’ perceptions determines the effectiveness of outcomes [17], [18], and [19].

Researches regarding the accuracy of manager’s perceptions have questioned the reliability of the manager’s perception [20]. The induction and deduction processes of turning abundant data into actionable knowledge seem to be the key [21], since sense-making plays a crucial role in this knowledge formation cycle.

Organizational sense-making is the creation of an environment which allows the employees to develop an agenda for change through the process of internalized group loyalty. The synergy created through the group sense-making will itself create confidence throughout the organization.

If one can connect the abstract with the concrete through experimentation then we can create an organization with can deal with crisis as a challenge with immediate actions, local context, and concrete
Moving towards Creating an Organic Lean Manufacturing Organisation

cues [23], and not a threat. Sense-making framework can again be a fundamental tool for the lean-fit organization.

As such one can argue that lean production in reality should be seen as the 'product workshop' culture and not a whole organization body. In that context lean must engage the organisational strength factors if competitive sustainability is to be achieved. If we were to assume this, perhaps we can then state with more confidence:

- Lean produces an operational environment that is highly conducive to waste minimization and focused production, which must be enriched by organisational strength factors in order to be self-creative and innovative. Lean methods focus on continually improving the resource productivity and production efficiency, which frequently translates into less material, less capital, less energy, and less waste per unit of production. OS factors will enable it to look beyond current requirement and explore a new pathway. Any activities which is supporting the creation exploration can no longer be assumed to non-value adding. We must therefore create three positions for all activities: direct value adding, indirect value adding, and non-value adding.

- Lean can be leveraged to produce more internal improvement, filling key “blind spots” that can arise during lean implementation. Their integration with OS factors will allow us to see external opportunities within internal improvement which allows us to create new markets, new products, and new human resource capabilities. Our people create tomorrow ahead of customer requirements.

5. SUMMARY

Lean manufacturing has helped organization competitiveness. We must however accept that its main focus is productive flexibility, process standardization, and systemization. It may be misleading to expend the concept of lean production as lean management or even lean organization. For organizations to survive the volatile global environments they must build in contingencies in their capability, structure, knowledge, and flexibility. It may be possible then to accommodate future business diversifications using the current workforce. The lean concept has been wrongly used as an excuse for outsourcing many capabilities which we need internally in time of change and economic uncertainty. It has also been an excuse for many senior managers for reducing workforce which do not directly create short term value. Investment in human resources has also been turned into training for short term compliance. Production culture has traditionally been slow to accept customer focused approaches. In the market place customer segmentations are not clearly separated any more. As customer find other means of creating buying power, companies must make sure their employees possess the same flexibility and innovation power. The current world economic crisis has shown the rigidity of our mechanistic views. In the two large manufacturing companies in the middle-east, the framework of lean manufacturing was enriched by the integration of work organization factors such as shared knowledge, cognition, and learning. This allowed and encouraged innovation beyond process refinement. Using the concepts of high-involvement management, and high-performance practices a further motivational framework was created. By in-depth integration of lean manufacturing, work organization, and human resource management an organic learning was achieved. The organizations were able to create an environment where high-involvement and commitment from management and employees are emphasized and required. In both cases not able results were achieved. Using the same workforce production targets rose by over 50%, the wastage declined by 67%, and employees suggested renovation and innovation of their processes and working systems. Delegation of decision making was seen as a crucial element of team-working, and a framework for sharing the benefits was developed. In this way the development of an organic lean manufacturing organization where the culture of commitment replaced compliance took place.

The strategic importance of ERP screening process: Evidence from the forging industry

Athanasios Klonis* and Ruben Pinedo-Cuenca
School of Science and Technology
University of Teesside
Middlesbrough, TS1 3BA, England

ABSTRACT

Enterprise Resource Planning (ERP) systems offer a certain degree of customisation, to accommodate different aspects of a business, but no ERP platform can be considered a panacea for every application. The selection of appropriate ERP software is a paramount factor for the effective execution of any implementation project. Whilst the selection criteria in large organisations have been based on actual organisational requirements, it has been observed that these are often overseen in small-medium enterprise over the software procurement costs. The initial capital expenditure savings may incur increased operational costs once the system is in use and other indirect costs such as people loosing confidence in using the system. The paper presents the findings of an ERP implementation project in the forging industry and discusses the challenges in tailoring the system to the business needs. The study is part of a larger improvement project being carried out in the company.

1. INTRODUCTION

The forging industry is one of the oldest metal processing industries [1]. This metal shaping technique changes a metal’s properties through heat treatment and hammering (hot forging) or through hammering at ambient temperature (cold forging). Whilst significant advances have been made in other metalworking industries such as casting and sheet fabrication, the forging industry still relies on rather old fashioned production methods and intensive manual labour activities. The old fashioned methods employed in the production systems are often reflected in the supporting pillars of process technology structures.

Developments in information processing technologies facilitated the computerisation of the set of procedures, data and knowledge used by the company to manage production and logistics to successfully deliver a product to the end customer [2] and also provided organisations with the opportunity to develop real-time linkages across the supply chain [3, 4, 5]. Enterprise Resource Planning (ERP) systems first appeared in the early 1990s and initially provided inventory control [6]. They were then expanded to include MRP and MRP II, and finally integrated all departments and functions of an enterprise such as sales and order management, marketing, purchasing, warehouse management, financial accounting and human resource management into a single business management system [7].

The benefits of ERP systems have been well documented [8, 9] as are the difficulties related to their implementation [10, 11, 12]. The benefits of ERP systems in large organisations, in addition to the lessons learned have made ERP plausible for small-medium enterprises [13]. These have previously been reluctant in investing in IT technologies [14] due to the complexity, duration and cost implications associated with IT implementations [15].

The implementation of ERP systems can be a difficult task [16] which can fail in spite of the large amount of capital and time invested [17]. The selection process of suitable ERP solution has been identified as a crucial task in the implementation process [18]. In the above studies, the authors acknowledge that one of the primary concerns for SMEs is cost, however they argue that the selection of the ERP software should not be made just on the basis of cost, as the operational implications could have a greater impact. Another study [19] explored the differences in the selection process in SMEs and large organisations and concluded that the priorities of the organisation in respect to ERP selection in addition to the selection process costs differ on the basis of size. The authors suggested that the selection criteria for large organisations included increasing organisational flexibility and enhancing supply chain relationships with customers and suppliers whereas for small-medium organisations, the criteria included cost and adaptability of the software.

In the absence of adequate empirical research in the implementation of ERP software in the forging industry, this study provides an overview of the implementation process, highlighting the issues and pitfalls for future adopters. The results of this case study suggest that cost is indeed the primary selection criterion for SMEs and present the operational challenges associated with the implementation of ERP software, selected purely on the basis of capital expenditure.

2. BACKGROUND

The company of this case study is a UK manufacturing SME specialising in the supply of bespoke components for critical engineering applications. The company’s headquarters and manufacturing facility are based in Scotland, whilst the forging plant is based in the North East of England. The forging facility is currently the home of 45 employees and has been operating since the 1970s, manufacturing chains and lifting tackle. In the early 80s the plant started manufacturing goods for the UK and Norwegian oil and gas industry and in the late 90s expanded its production facilities to handle large forging work that was previously outsourced.

The forging plant installed its first management information system, built on MS DOS, in the late 80s. According to the general manager, the system was state of the arts at the time, and included modules for handling accounts, creating sales orders and production route cards and controlling stock but lacked important capabilities such as estimating and production modules. Activities such as creating estimates, raising quotes, quality and dispatch documents were carried out using external applications such as departmental databases, spreadsheets and word documents. Albeit employees were rather comfortable using the DOS system, the latter failed to communicate information adequately across the departments and did not provide real time stock visibility, causing major delays and problems in the business. As a result duplicate data entry was a common occurrence across all departments taking as much as 50% of the orders lead time. In spite of the laborious information checks from the quote stage to the production stage the quality of entered information was questionable. This had unwanted effects on two accounts: first it jeopardized the quality of information handled by the business, and second it increased the order processing time before the creation of a route card, consuming valuable lead time.

Over the last twenty years the business was temperamental due to the uncertainty in the oil and gas market. Recently however, the company was given the opportunity to grow significantly from £ 3.5 million turnover to £ 8 million, as it was designated as the preferred supplier for a large multinational organisation. The subsequent increase in sales volumes raised the amount of paperwork exponentially, to the degree where valuable time was lost due to the inefficiency of the legacy system. The company had already installed an ERP system in its manufacturing facility in Scotland; which albeit not being used to its full capabilities had resulted in significant reductions in data entry and processing time. Following this implementation, management moved with the purchase of additional licences to replace the aged DOS management information system in its forging facility. Unfortunately the implementation of the system in the forging facility was not as straight forward as initially thought, and after two years of purchasing the additional licences, the company was still using the legacy system. With plans to grow substantially by 2011 and in an attempt to effectively accommodate the rapid and demanding changes the company liaised with Teesside Manufacturing Centre (TMC) to:

- Implement the ERP software.
- Introduce a continuous improvement culture within the production workforce
- Reduce lead times for handling orders and generating route cards
- Introduce adequate stock and quality control mechanisms.
- Eliminate duplicate data entry
- Streamline laborious processes to control specialized customer requirements.

3. TIE-CHI METHODOLOGY

The implementation of any improvement initiative has been reported to yield changes in the organization, which are viewed reluctantly and resistively [22]. The project was carried out applying a proof methodology developed by TMC and well-recognised in the North-East of England. The methodology, known as Total Integrated Enterprise (TIE-CHI) [20, 21] was developed to overcome the main implementation challenges regarding management and cultural change. Different from traditional approaches, the TIE-CHI methodology uses a dual approach to ensure
from the outset of the project, the top management support and commitment, and the ownership of the project across middle-management and workforce. The methodology entails three stages:

- **Consensus**: to create consensus of the needs and priorities of the business across the management layers of the organisation,
- **Homing-in**: to define strategic, tactical, operational, technological and cultural needs and gaps,
- **Implementation**: to embed the selected initiatives in the organisation.

Upon completion of the Consensus stage, the management team was made aware about the need to enhance business practices and systems in order to remain competitive in the current economic environment. Business needs and priorities were defined and communicated to the rest of the organization in order to condense the resistance to change by getting people motivated and involved with the implementation [23]. After the whole organization was aware of the importance of the project, the Homing-in stage was initiated, where workforce and medium management was involved to define the needs and gaps of the organization from the social, cultural, technological, operational and strategic point of view. The authors held an introductory session highlighting the unique opportunity for the implementation team to re-engineer their business processes by proposing new and innovative ideas, incorporating best practices based on the actual company needs, rather than trying to mimic current practices. Bearing in mind the company’s constraints and company priorities and needs, the implementation was divided into two phases. Phase 1 included enquiry and sales process, engineering, quality, production planning and stock control. Phase 2, which is still ongoing, included advanced manufacturing practices, business performance measurement and integration with lean practices.

Process maps captured during the homing-in stage were fleshed and analysed to define gaps and limitations of systems [24]. During this process, participants were challenged to re-engineer current practices in paper by emphasising weakness in their practices and reflecting upon the need for change using the 5-Whys approach. At the end of the exercise, participants were able to perceive how their processes could contribute to achieve the business objectives and fulfilling the needs of the business. Each participant was able to experience how the system will overcome limitations with current practices and fulfilling the initial expectations. However, there were occasions where the system could not satisfy the initial expectations regarding process, data, and analysis and post-it notes where attached to the step in question as shown in Figure 1.

![Figure 1: Process Maps](image)

The process maps were further developed using process activity mapping and the lean principles of eliminating waste or non-value adding activities. The application of lean principles and the cultivation of a continuous improvement environment have been used successfully in other studies see for example [25, 26]. The process activity mapping highlighted the opportunities for improvement and the areas that the new system would replace. This approach assisted the team to visualise the areas required for change and areas directly or indirectly affected, but overall, smoothing the negotiation process when the adoption of new process involved the introduction of new tasks to other departments.
At the enquiry and sales stage, the company received an average of 300 enquiries a month, at an order conversion rate of 25%. The company’s target was to generate a quote within 48 hours from receiving the enquiry; however this was hardly accomplished, as over 32 enquiries had to be handled daily. Upon receiving an enquiry, an enquiry number was manually recorded at a logbook. A hard copy of the enquiry was passed onto the estimator who used an access database to generate the quote, which was then communicated to the customer. If the quote was successful, the same information was re-entered into the DOS system to enable the creation of the Work Order. The process was cumbersome with multiple duplicate data entry stages and failed to provide adequate traceability relative to the order. In addition, there was no system in place to record the reasons behind lost enquiries, and the company failed to chase lost enquiries which had an impact on sales.

All accepted sales orders were passed on to engineering for the work order route cards to be created. These were generated using the DOS system. Different route templates were available for the different grades of materials and for different material processing specifications, enabling the user to select and create the route card in a straightforward manner. The DOS system listed the quantity of material available in stock, but failed to provide visibility of any material being allocated to a particular job. As such, there were instances where route cards reached the shop floor listing material reserved for other jobs, creating upset and delays in the processing of the orders.

The delays in processing route cards were prolonged further due to a significant amount of time spent at the quality stage to ensure all information on the route cards was correct and caused an adverse effect on quality. Any changes required were marked on the route card hard copy and passed back to engineering. If no changes were required, the Route Card was passed on to Production to be planned. Quality was the most important part of the business as all products had to be made according to rigorous specifications and all material had to comply with the exact customer specifications. This required an immense amount of paperwork which was created by a combination of word documents and outputs from the DOS system.

Production planning was another grey area within the company, as it simply followed the first in first out rule. Every job passing through the quality stage was entered into the production plan and was driven by the required despatch date. There was no indication of actual lead times and monitoring of WIP relied on shop floor employees who used a series of spreadsheets to record the completed stages of each job. In effect, the process of updating the production plan was time consuming and involved a significant amount of manual data entry. Without any means of prioritising jobs, orders were often late which affected the delivery performance.

4. IMPLEMENTATION CHALLENGES

It is widely accepted that ERP implementations can be lengthy and complex [27, 28, 29]. The main obstacles during EPR implementations fall broadly in four categories; people cooperation and commitment, cultural change, systems capabilities and knowledge base and learning process.

In this study people cooperation and commitment was not really an issue, as all employees did their best to fulfil their everyday tasks and their roles in the implementation. However, the load of the daily activities of some employees did not allow them to participate as much in the implementation, impacting on the project plan and creating conflicts of interests with other departments that had the opportunity to progress faster with the implementation.

Cultural change is a difficult process to manage, as it may be obstructed by a large number of factors. In this study, cultural change was threatened mainly by people’s fears of becoming redundant as their daily tasks could be significantly reduced or even eliminated; losing control of their functional areas or not being able to hide inefficiencies. These factors were overcome with the assistance of top management which ensured their positions were not at risk and by educating people in best practices and continuous demonstrations of how the system would mimic their systems in a more effective manner, enabling them to be proactive rather than reactive.

The system capabilities has an important role in the implementation process, due to the complexity added to the re-engineering process to adapt the business processes to the system or otherwise, to customise the system accordingly to the business as illustrated in Figure 3. If the software can not handle aspects necessary for the success of the business, then this will have a significant impact on the project costs, duration and expectations point of view, unless project risks are defined and mitigated. The ERP software in this study was chosen on the improvements realised in a precision machining environment, which is largely differentiated from a forging environment. It was soon evident that the system presented significant limitations to cope with some of the key priorities and needs for the business. In a precision machining environment, part costs are easily calculated by considering material costs, sub contract costs, setup and run costs, tooling costs and labour hours. The operations and machine utilisation are
more closely monitored and more in depth visibility may be obtained. The forging industry dates back many decades and traditionally the cost associated to forging a job is rather arbitrary calculated by taking into account the shape difficulty factor and the “material difficulty factor”, or forgeability (the ability of the material to deform without failure regardless of the pressure and the load applied) [30] [31].

Figure 2: Adaptation strategy

In an effort to reduce capital expenditure, the company had signed an agreement with its raw material supplier, for the provision of consignment stock. The company was supplied raw material billets at regular intervals and was charged for the amount of material that had been consumed each month. The ERP solution did not distinguish between standard stock and consignment stock. Therefore, the raw material cost was input when the material was booked in and not when the raw material was used. As a result, the system provided inaccurate financial information including material expenditure, stock value, job margins, invoicing, etc when consignment stock was used.

The importance of quality in the nature of business has already been highlighted. Full traceability from raw material to end product was a paramount quality requirement, as were the non conformance reports (NCR). The ERP solution did not have any functionality for inputting the raw material composition, used to identify suitable material of a particular composition. In addition, the ERP solution did not include a sophisticated quality module to handle the activities carried out by the quality control department such as recording mechanical test results and inspection results. The user was able to create NC reports; however this functionality did not restrict the user to issue material to next operations, harbouring the risk of moving unapproved material that has failed an inspection stage through the remaining production stages.

The vendor committed to develop part of these functionalities within an agreed timescale free of charge, however these had to be aligned with the vendor’s strategy for software development. Although this was a major risk for the overall implementation as all delays in delivering the promised functionality could impact on costs associated with the development of reports, the vendor delivered some of the required functionality enabling the team to create a solid solution definition for the company. The stock issue was resolved and the system was able to hold all the necessary information relative to the material composition, enabling the users to record the majority of the test results. However, certain aspects of the business such as estimating and creation of test certificates had to be handled by external applications and reporting mechanisms until the software vendor was able to incorporate these changes in the system.

Knowledge base and learning process can also impact the implementation process. In this occasion, age, limited IT skills and lack of theoretical background in ERP concepts where the main obstacles that affected the performance and speed of the implementation. Key people in the process found difficulties to retain the processes or understand the need from a strategic perspective. This was overcome by using a deep-learning approach, supported with special
training material designed to support learners. The use of e-learning material contributed to smooth the familiarisation of the user with the system.

5. PILOT AND PREVENTATIVE TROUBLE SHOOTING

Going live is a major challenge for any organisation. Solutions definitions generally follow the 80/20 rule, leaving 20% of processes untested as being perceived as sectional cases. However, the lack of understanding of the implications of these processes can jeopardise the efficiency of the system and distort information crucial for the management of the business. To minimise this risk and ensure that no processes had been neglected, the system was set according to the Solution Definition and employees were asked to use the system in parallel to their current system. The team decided to pilot a large order from their main customer. The team used the system to log the enquiry, create the quote, raise the sales and work orders and issue the WO to the shop floor. The pilot project highlighted some minor concerns previously missed during the training sessions; however they did not result in any major changes in the design of the process. After resolving the issues highlighted in the pilot, the company went “live” with the new ERP solution nine months after the start of the project.

6. IMPLEMENTATION BENEFITS

The potential benefits derived from ERP systems have been well documented in literature. These can differ from company to company as they are directly related to the company’s attitude to the project and the use of a sound methodology and skills to drive the implementation. To date, the company has been able to realise significant benefits through the ERP implementation. These have been distinguished in relation to the process studied (Table 1) and in relation to the business as whole in Table 2.

7. SUMMARY

The paper presented an ERP implementation case study in the forging industry using the TIE-CHI methodology. The key steps undertaken in the project were outlined, highlighting the adaptation process and the implementation challenges and their implications relative to time and costs. The results of the study support the argument of other studies [32, 33, 34] and suggest that a rigorous selection process should be undertaken prior to the purchase of an ERP platform to avoid the risk of re-investing in an ERP solution. ERP systems are not designed for every application, and what works well in one environment may not work in another.

A working solution was delivered at the end of the study and the company went live with its new ERP system, realising significant benefits, both tangible and intangible. The intangible benefits of the organisation, were monitored at different stages of the project in order to identify changes in people’s perception about the organisation and the project. From the comparison, between the stage before to start the project and after the going live, the company recognised having changed to some extent their attitude regarding taking ownership of their processes to improve them and assist other functional areas. Furthermore, the authors also noticed significant changes in people’s involvement, changing from being spoon-fed and reluctant to use the system, to becoming very demanding regarding using additional functionality of the system, extracting management information from the system and monitoring key activities of the business. In addition, workforce seemed to work using a more holistic and integrated approach, feeding information to other departments as data concerns were raised.

ACKNOWLEDGEMENTS

The authors would like to thank One North East for partially funding this project and all the employees for their help and cooperation during this study.

REFERENCES

Product/process design and optimization is typically aimed at manufacturing a single product for a single customer, and often leads to underutilization of the available production capacity. Thus it is reasonable for a manufacturer to make an effort to minimize or eliminate that excess capacity to achieve high effectiveness. Excess capacity can be allocated by running multiple products/processes design and optimization independently of the first. However, exploring possible synergies between the two (or more) products/processes may bring even higher benefits.

This paper presents a case where a manufacturing process (plastic blow molding) was shared between two different products for two different customers with two different sets of needs. These customer needs were mapped into core value-creating processes, recognizing both the differences in their requirements as well as the similarities in their expectations. Conflicting differences in production volumes and quality requirements were reconciled leading to higher customer satisfaction and improved cost performance.

That was achieved by using an innovative approach in applying Quality Function Deployment (QFD) simultaneously to both sets of customer requirements, analysis of synergies and conflicts within each and also between the two. The goal was to find the common operating range to fulfill entirely both sets of customer expectations, under assumption that an overlap existed.

The effort focused on processes for two products: C1 and C2, where the challenges included: (i) strong process coupling (over 60%), (ii) product differences (in terms of feature complexity, production volumes, cycle times, and quality requirements). Application of the proposed approach resulted in a revised production line layout, which led to reduced scrap rates (below 1%) and increased production rate (by 24%).

1. INTRODUCTION

Quality Function Deployment (QFD) has been used extensively in the last few decades to generate a bridge between the Voice of the Customer (VoC) and Process Parameters, [1, 8, 9]. The two extremes of Product Design seem so far apart that many times, by the time we finally arrive to defining the Process Parameters there is no link between them. The journey from one end to the other includes: VOC, Critical to Satisfaction (CTS) elements, Functional Requirements (FR), Design Parameters (DP) and Process Parameters (PP). By using QFD, many successful companies reduced dramatically the Product Development cycle while increasing the Customers’ satisfaction, [6, 7].

This paper attempts to go beyond the common use of QFD methodology. It is rather rare for a company to have only one customer or to have the resources to deal independently with multiple customers. Nowadays, in order to survive, the companies need to continuously optimize the use of available resources while maintaining a high quality standard. We attempt to develop a methodology that would explore QFD and other concepts in resolving conflicts between multiple customers that have different needs to be addressed simultaneously in order for the supplier to be competitive, [6, 8]. At a minimum, the paper will provide a methodology that would allow companies to make the right decision when faced with the challenge of coupling or decoupling the simultaneous fulfilment of the needs of different customers.
For simplicity, the paper addresses the case of three different entities that compete for the same pool of resources: External Customer 1 (C1), External Customer 2 (C2) and the Internal Customer (C0). To add complexity, C2 requires two different product lines: C2-I4 & C2-V6. As mentioned in the Abstract, the needs of the two external customers are very different and they both differ from the needs of the C0.

The methodology will be elaborated upon a real life example that will prove what can happen if a proper analysis of the conflicting requirements is not performed in advance.

2. QUALITY FUNCTION DEPLOYMENT - QFD

2.1. Defining Customer Requirements and Critical to Satisfaction criteria

Quality Function Deployment, according to the definition in Dr. Akao’s book, [1], “provides specific methods for ensuring quality throughout each stage of the product development process, starting with design. In other words, this is a method for developing a design quality aimed at satisfying the consumer and then translating the consumers’ demands into design targets …”

As mentioned before, this paper attempts to optimize resources by using an innovative approach while meeting – or exceeding – multiple customer requirements. In Fig. 1 Mind Mapping was used to identify and cluster VoC. The paper deals with two external – C1 & C2 – and one internal – C0 – customers.

![Fig. 1 – CTSs deployment](image)

The “fuzzy” customer requirements were analysed and clustered in three categories: Cost, Quality and Delivery. In-depth analysis followed not only in identifying the Critical to Satisfaction criteria but also in benchmarking the plant performance against Best-In-Class. The first analysis is presented in Fig. 2.

Analysis of the 1st House of Quality – HOQ1 -:

- Customer requirements differ considerably between C1, C2 & C0. A short list of the major differences:
  - levels of complexity – C1 has 75% more components then C2 -;
  - production volumes – Vc2/Vc1 = 2 -;
  - cycle times - Tc1/Tc2 =1.5 -;
  - quality requirements – Qc1 > Qc2 -;
  - delivery – C1 expects JIT vs. C2 forecast based –

- There is a considerable gap in performance based on both, customers’ perception and internal performance;
- VoC elements on the left hand side of the house are listed in the order of importance; It can be observed that customer C1 is focused on quality versus customer C2 - on cost;
- In the “roof” of the HOQ1 we can observe the conflicts between CTSs; The major conflicts are between the # of Blow Molders (BM) & Assembly Lines on one hand and Days on Hand (Available Inventory of Finish Goods) & quality on the other hand.
2.2. Next step in our methodology is to analyze CTSs against FRs.

Some of the conclusions we can make based on HOQ2 – presented in Fig. 3 - are:
- The order of importance of FRs is very similar to CTSs and VoC s: Quality, Delivery and Economies of Scale; The challenge that this paper addresses goes beyond the traditional tripod balancing – Quality, Delivery & Cost – as each “conflicting” CTS has a different customer behind;
- Economy of scale conflicts once again – as seen in the “roof” of the house – with requirements related to Quality & Delivery

2.3. The last iteration of our QFD analysis is the analysis of the DPs against FRs.

Some important points in the analysis of HOQ3 shown in Fig. 4:
- The two most important DPs based on the previous analysis are: Two-way communication & Management System and Independent Value Streams (VS) – e.g. design independently the VS for C1 from the VS for C2
- In the “roof” of the HOQ3 – the contradiction area - we can clearly identify the main conflict between the independent Value Stream design and the requirements related to Cost - very important to both, C2 & C0;
- The final design needs to consider all the conflicts identified throughout the QFD development and either eliminate them or minimize the adverse effects.
3. DEVELOPING DESIGN CONCEPTS – PUGH MATRIX

Based on the QFD analysis, design concepts have been developed attempting to meet all the customers’ requirements. A summary of the designs – Fig. 4 – is followed by a Pugh Matrix analysis - Fig. 5 -.

The Datum against which all the proposed designs were evaluated consists of the initial design: Integrated BMs, coupled C1 & C2 and, within C2, coupled down-lines (DL) C2-I4 & C2-V6. The initial design was chosen without considering all the main elements required in order to meet the VoCs. That approach led to major conflicts throughout the manufacturing chain that could not be resolved.

Based on the Pugh Matrix analysis we can conclude the following:

- There is no “ideal” design as the three customers have very divergent requirements;
- 4 out of the 6 proposed designs are better options than the Datum;
- The 2nd best design – D1 – 100% Independent VS – meets most of the C1 & C2 requirements although it is unacceptable to C0 due to the very high cost associated;
- The best design – D3 – Independent BMs, independent DLs C1 & C2 and coupled C2-I4 & C2-V6 – is a compromise between the 3 opposite requirements;
4. APPLICATION OF THE METHODOLOGY IN A REAL LIFE INDUSTRIAL EXAMPLE

4.1. Case introduction and problem definition

The manufacturer of automotive products C₀ supplies directly to two different customers: C₁ & C₂. Due to targeting opposite sides of the market – luxury vs. high volume/low cost - the two customers have very different requirements – e.g. C₁ has the major focus on the quality of the product and timely delivery whereas C₂’s focus is first and foremost in cost reduction and diversity of the product – two versions: I4 & V6.

The design that was originally chosen is the Datum in our Pugh Matrix analysis: integrated BMs, coupled C₁ & C₂ and, within C₂, coupled DLs C₂-I4 & C₂-V6. That was mostly driven by the C₀ as the design met all the main requirements focused around economy of scales – e.g. using one BM for both, C₁ & C₂, one gantry system and one DL for both versions of C₂.

As shown in Fig. 6, the BM is shared by the two customers. On addition, due to the common gantry system designed to transfer the part to either one of the DLs but not to both simultaneously, the two customers could not build in parallel. Obviously, this design puts a lot of pressure not only in scheduling, but also in the way the lines are controlled and managed.

The design delivered very inconsistent results. Among other performance metrics, the scrap produced by the BM is presented in this paper. In Fig. 6 we can see in the embedded P-Chart that the average scrap rate was over 20%, [2]. That is an extremely high level comparing not only with outside competitors but also vs. other Value Streams in the plant. The delivery was also very poor requiring repeatedly expedited shipments to the customers due to the shortage of parts.

4.2. The solution

The situation required a return to the drawing board and a complete redesign of the production lines. A quick analysis was made and, based on it, a design where the BM is shared but the two external customers are completely decoupled was chosen. Going back to our QFD analysis, we have already identified that the best design, considering the constraints, is decoupling completely the two customers – including the BMs -. However, even if the chosen re-design was not the optimum, decoupling completely the assembly lines improved dramatically the business metrics.

In order to facilitate the decoupling, process optimization was initiated with the following goals shown in Fig 7:

- Reduce the travel of the Associates;
- Re-program the welder, a key piece of equipment in the assembly of the parts;
- Replace automatic scanners with manual;
- Introduce a new mistake-proofing station to reduce the rework for C₂;
- Re-balance the line so the manpower does not change with the introduction of the new station;
- Open a logical gate at the back of the feeding conveyors in order to improve the flow, [3, 4].

Fig. 6 – Initial Design with the Scrap P-Chart

Fig. 7 – Process Optimization on C2 – Section of Fig. 6

Fig. 8 – Constraints Reduction Chart

In Fig. 8 we can see the reduction in the design constraints by decoupling the DLs. The re-design is identical with Design 2 in our Pugh Matrix chart. We notice that the BM is still shared – that is against our best identified design – as well as the DLs for C2 – this time the decision is aligned to our best D3 solution.
4.3. The new layout

The major change in the new design stands in the decoupling of the two assembly lines: C₁ & C₂. Beyond the fundamental improvements identified by the Pugh Matrix, additional benefits turned a very problematic manufacturing process into an acceptable one that carried on the production until customer C₂ discontinued its product. Some of the technical and management improvements are listed below:

- A logical gate was designed & installed at the end of the input conveyor after the BM –Fig. 9--; That allowed a better management of the production – e.g. in case of assembly issues down the line the shells were recuperated and introduced back once the assembly line issues were solved; An expansion/contraction study was required in order to validate the reuse of the unfinished product;
- Customer C₁ was relocated in such a way that access from both sides was provided to the Associates; That solved many of the production issues, allowing a more efficient distribution of work as well as easier access to replenish the inventory, [5];
- Incremental steps were taken towards improving both assembly lines from the flow as well as safety & ergonomics perspective;
- One of the major improvements that allowed a much better scheduling based on customer demand was change over reduction on the BM;

Fig. 9 – New Layout

4.4. Improved metrics

In Fig. 10 we can see the dramatic improvement in the scrap level generated by the BM from over 20% to below 1%, [2]. All the improvements mentioned above had contributions to the improved performance.

In Fig. 11 we can clearly see the positive trend throughout the improvement cycle. Also, although definitely correlated with the reduced amount of scrap, a significant improvement occurred in the number of parts produced from an average of about 525/day to over 650/day – 24% increase -. There is still a relatively high variation in the output that would definitely be addressed by choosing the design with the highest score in the Pugh Matrix analysis: D3 – independent BMs -.
5. SUMMARY AND FUTURE WORK

This paper developed a methodology that allows a company to resolve conflicts between multiple customers that have a rather wide range of needs. That is solved by using concurrently and innovatively concepts used traditionally either in Process or Design Optimization. The methodology was applied on a real manufacturing process faced with the above mentioned challenges. While an ideal solution might not be always possible, by applying the concepts presented in this paper companies could resolve either entirely or partially the conflicts generated by multiple customers requiring access to a limited pool of resources.

A logical continuation of this type of effort would be to verify the usefulness and applicability of the methodology in other fields – e.g. healthcare, food industry, academia, retail etc. –. The researchers plan also on expended the methodology by engaging business concepts – e.g. Evidence Based Management, Advanced Statistics etc. –. Considering that the attempt will be successful, the methodology will allow companies to make the right decision – from all three perspectives: Business, Design & Process - when faced with the challenge of coupling or decoupling the simultaneous fulfilment of the needs of different customers.

CAD of Main Spindle and Feed Drives for CNC Machine Tools

Zoran Pandilov* and Vladimir Dukovski

Department of Production Engineering,
Faculty of Mechanical Engineering, University "Sv.Kiril i Metodij"-Skopje
MK-1000 Skopje, Republic of Macedonia

ABSTRACT

Characteristics of main spindle and feed drives highly depend upon skillfulness of composing variable speed motors (AC or DC) and mechanical transmission elements. In order to enable interactive computer aided design and analysis of different design variants of CNC machine tool drives, original computer programs have been developed.

1. INTRODUCTION

This paper presents our investigation of principles for analysis and design of CNC machine drives. Contemporary development of machine tools highly depends on improvements in drive systems.

A special feature of CNC machine tool drives is use of variable speed (AC or DC) motors which provide continuous changing of cutting speed and feed rate.

The use of variable speed motors creates a question of their appropriate composing with mechanical transmission elements in order to get better output characteristics and to satisfy some conditions as a system.

2. THEORETICAL CONSIDERATIONS AND COMPUTER PROGRAM FOR DESIGNING MAIN SPINDLE DRIVES FOR CNC MACHINE TOOLS

Main spindle drives for CNC machine tools must provide constant power at wide range of speeds on the output of the main spindle. They consist of three parts: 1. variable speed motor, 2. mechanical transmission elements which provide appropriate output characteristics of the main spindle and 3. main spindle.

Usually mechanical transmission elements consist of: belt transmission or combination of belt transmission with gearbox (with two, three or four speeds).

Intensive development of quality tool materials enable using of very high cutting speeds and power.

Necessary output power on the main spindle can be calculated as:

\[ P = \frac{F_t \cdot v}{60 \cdot 10^3} \text{ [kW]} \]  

where: \( F_t \) - tangential cutting force component [N]; \( v \) - cutting speed [m/min].

CNC machine tools are used for production of workpieces with different shapes, dimensions and materials, with wide range of cutting data.

For ensuring these requirements the speeds on the main spindle must be regulated in very wide range,

---

* Corresponding author: Tel.: (389 2) 3099-259; Fax: (389 2) 3099-289; E-mail: panzo@mf.edu.mk
\[
R_{ms} = \frac{n_{max}}{n_{min}} \cdot \frac{v_{max}}{v_{min}} \cdot \frac{D_{max}}{D_{min}} = R_v \cdot R_d
\]

where: \(R_{ms}\) - range of regulation of output main spindle speeds; \(R_v\) - range of regulation of cutting speeds; \(R_d\) - range of diameters of the parts, or of the cutting tools; \(n_{max}\), \(n_{min}\) - maximal and minimal main spindle speed; \(v_{max}\), \(v_{min}\) - maximal and minimal cutting speed; \(D_{max}\), \(D_{min}\) - maximal and minimal diameters of the parts or the cutting tools.

According to our empirical investigation the range of regulation of main spindle speeds for CNC machine tools usually is within \(R_{ms}=20-350\) (exclusively rare to 600). Such kind of wide regulation of main spindle speeds needs particular attention in selection of variable speed motors and mechanical transmission elements.

Fig. 1: Power-speed diagram of variable speed AC motor

Fig. 1 presents power-speed diagram of variable speed motor, where \(n_{min}, n_{nom}, n_{max}\) are minimal, nominal and maximal speed of the motor, and \(P_m\) is nominal power of the variable speed motor.

Usually range of regulation of speed at constant power of variable speed motors is (2-8) (sometimes reaches values 12-16), which is far below required range \(R_{ms}=20-350\).

The overall range of regulation of output main spindle speeds can be calculated as:

\[
R_{ms} = R_{msm} \cdot R_{msp}
\]

where: \(R_{msm}=2-50\) - range of regulation of main spindle speeds at constant torque; \(R_{msp}=2-45\) (exclusively rare 70) - range of regulation of main spindle speeds at constant power.

There are two alternative methods of obtaining wide range of main spindle speeds at constant power: overrating of the AC or DC motor or combining the motor with gearbox with two, three or four speeds.

The second solution with two, three or four speed gearbox is widely used at the CNC machine tools.

Selecting the number of steps \(Z\) of the gearbox is in the range of regulation of the variable speed motor with constant power \(R_{mp}\), while with using the range of variable speed motor with constant torque \(R_{mm}=R_{msm}\) the whole range of regulation of output speeds of the main spindle is obtained [9,7,6].

Because of that, we can write:

\[
R_{msp} = R_{mp} \cdot R_z
\]

where: \(R_{mp}\) - range of regulation of variable speed motor with constant power; \(R_z\) - range of regulation of the gearbox. Variable speed motor can be treated as a particular group of gearbox with continuous changing speeds, which is first in the kinematic chain, with infinitely large number of transmissions, with transmission ratios which obtain geometrical progression with progression ratio \(\varphi \rightarrow 1\) and range \(R_{mp}\).
Gearbox can be treated as a transmission group which extend the speed range of the motor at constant power. Because of that characteristic of a transmission group $\Phi_z$ is:

$$\Phi_z = R_{mp} \cdot \varphi$$  \hspace{1cm} (5)

Because $\varphi \to 1$, we obtain

$$\Phi_z = R_{mp}$$  \hspace{1cm} (6)

As,

$$R_z = \Phi_z^{(z-1)}$$  \hspace{1cm} (7)

we can write

$$R_z = R_{mp}^{(z-1)}$$  \hspace{1cm} (8)

With the substitution equation (8) in (4), we get

$$R_{msp} = R_{mp} \cdot R_{mp}^{(z-1)} = R_{mp}^z$$  \hspace{1cm} (9)

where: $Z$-number of speeds of the gearbox.

With known $R_{msp}$ and $R_{mp}$, using the equation (9), we can calculate the necessary number of speeds of the gearbox $Z_E$:

$$Z_E = \frac{\log R_{msp}}{\log R_{mp}}$$  \hspace{1cm} (10)

The equation (10) is recommended also in the literature [9,7,6].

Fig.2: Diagram P-n of the main spindle a) with $z=3$ and b) with $z=2$

Because $Z_E$ is usually a decimal number, it is round to the nearest full number.

If $Z > Z_E$ we get characteristic with overlapping speeds (fig.2a).

In case $Z < Z_E$ we get characteristic with step decrease of the power $\Delta P$ (fig.2b).

For example, if from equation (10) we get $Z_E=2.5$, than $Z$ can be 2 or 3.

In case of $Z=3$ we get P-n characteristic as in the fig. 2a, and if is accepted $Z=2$ we obtain characteristic as in the fig. 2b.
Percentual decrease of the power $\Delta P$ in relation with the nominal power $P_m$ of the motor, when $Z < Z_{E}$ can be calculated with the equation (11),

$$\frac{\Delta P}{P_m} = \left(1 - R_{m_p} \cdot \frac{Z_{E}}{Z} \right) \cdot \frac{R_{m_p}}{R_{m_{sp}}} \cdot 100 \%$$

(11)

Usually $\Delta P/P_m$ should not be greater than 30% [9,7,6].

The above algorithm is implemented in an original computer program written for PC in C language which enables interactive design and analysis of main spindle drives with different design characteristics.

3. THEORETICAL CONSIDERATIONS AND COMPUTER PROGRAM FOR DESIGNING FEED DRIVES FOR CNC MACHINE TOOLS

The feed drive consists of an electromotor and mechanical transmission elements. The mechanical transmission elements comprise all the machine parts which lie in the torque (power) transmission flow between the servo motor and the tool or workpiece. In different design variants the following mechanical transmission elements are most frequently used: clutches, ball lead screw and nut units, rack and pinion units, bearings, gears, gearboxes (planetary, cycloidal, harmonic), toothed belt gears, guideways etc.

The main task in the feed drive design is a selection of a servo motor and mechanical transmission components. During this process the drive angular nominal frequency $\omega_{od}$ and nominal angular frequency of the mechanical transmission elements $\omega_{omech}$ are calculated.

In order not to affect the properties of the highly dynamic AC or DC servo motor, the nominal angular frequency of the mechanical transmission $\omega_{omech}$ elements must be higher than the drive nominal angular frequency $\omega_{od}$.

According to [1,10,6]

$$\frac{\omega_{omech}}{\omega_{od}} \geq 2$$

(12)

is recommended.

To satisfy the requirements and to enable a long exploitation period particular attention has to be paid to the selection of feed drive servomotors. An improper servo motor selection results in a less efficient operation of machine tool and a short exploitation period.

Total load torque $M_{tot}$ can be calculated as:

$$M_{tot} = M_{mf} + \sum M_{fl} \quad \text{[Nm]}$$

(13)

where: $M_{mf}$ is a torque caused by the machining force [Nm]; $\sum M_{fl}$ is a sum of torques caused by friction and losses [Nm].

The next step is a calculation of the necessary motor speed $n$ for a rapid feed rate.

The selection of a variable speed motor can be from a catalogue, or from an appropriate data base, developed during the investigation [6].

The total moment of inertia $J_{tot}$ can be calculated as:

$$J_{tot} = J_m + J_{ext} \quad \text{[kgm}^2\text{]}$$

(14)

where: $J_m$ is a motor moment of inertia [kgm$^2$]; $J_{ext}$ is an external moment of inertia reflected on motor shaft [kgm$^2$].

Equations necessary for calculation of $M_{tot}$, $n$ and $J_{tot}$ for different design variants are given in details in [1,6].
After calculation (Mtot and ne), for the selected servo motor an analysis of dynamic behavior must be performed.

With a dynamic behavior analysis, we calculate the acceleration time to rapid traverse feed rate for loaded motor ta, nominal angular frequency of the drive \( \omega_{od} \) and position loop gain \( K_v \).

The acceleration time to maximal speed for loaded motor \( ta \) can be calculated as:

\[
ta = \frac{J_m \cdot n_m}{9.55 \cdot M_a} \cdot 10^3 \quad \text{[ms] (15)}
\]

where: \( n_m \) is maximal motor speed \([\text{min}^{-1}]\); \( M_a \) is acceleration torque \([\text{Nm}]\).

The acceleration time to maximal speed of unloaded motor \( tb \) is:

\[
tb = \frac{J_m \cdot n_m}{9.55 \cdot M_a} \cdot 10^3 \quad \text{[ms]} (16)
\]

The acceleration time to the maximal speed of unloaded motor \( tb \) is given in a motor catalogue. If \( tb \) is not given directly, it can be calculated indirectly by the maximal angular acceleration of the motor shaft \( \alpha \) [rad/s^2].

Because

\[
M_a = J_m \cdot \alpha \quad \text{[Nm]} (17)
\]

equation (16) becomes

\[
tb = \frac{n_m}{9.55 \cdot \alpha} \cdot 10^3 \quad \text{[ms]} (18)
\]

With the substitution of equation (16) in (15)

\[
ta = tb \cdot \frac{(J_m + J_{ext})}{J_m} \quad \text{[ms]} (19)
\]

If \( ta \) is greater than a permitted value, corrections are made in mechanical transmission components (transmission ratio, feed screw lead etc.), in order to reduce \( ta \) and to satisfy the necessary value.

For an approximate mathematical calculation of nominal angular frequency of the drive \( \omega_{od} \), model shown in fig.3 [1], can be used.

\[
\omega_{od} = \frac{1}{T_{eld}} \left[ 1 + \frac{1}{2 \cdot \frac{T_{mech}}{T_{eld}}} \right] \quad \text{[s}^{-1}] (20)
\]
where: Teld is a drive electrical time constant [s]; Tmechd is a drive mechanical time constant [s].

Another important element which can be approximately calculated is the position loop gain $K_v$.

The position loop gain $K_v$ is a ratio of nominal speed $v_n$ [m/min] and difference between nominal and actual position $\Delta x$ [mm].

$$K_v = \frac{v_n}{\Delta x} \left[ \frac{m}{min} \right]$$

$$K_v = \frac{1000}{60} \frac{v_n}{\Delta x} \left[ s^{-1} \right]$$

The analysis in [1] shows that in ideal condition the optimal value of $K_v$ must lie in the range of:

$$0.2 \cdot \omega_{od} \leq K_v \leq 0.3 \cdot \omega_{od}$$

(23)

For real conditions it is recommended:

$$K_v < (0.2-0.3) \cdot \omega_{od}$$

(24)

The calculated values for $K_v$ from equations (23) and (24) are approximate. The exact value can be obtained experimentally by the numerical control of machine tool [6,8,2,3,4].

One of the most important requirements for good dynamic behavior of the feed drive is high acceleration of the CNC machine tool slide due to the demand for minimal mechanical time constant [1,5,6]. Magnitude of inertial forces which directly affect the accuracy depends on the magnitude of slide acceleration.

Acceleration limits are recommended [1,5,6]:

- for machine tools with normal accuracy ($a_{per} = 0.8-1.5 \text{ m/s}^2$),
- for machine tools with greater accuracy ($a_{per} = 0.2-0.4 \text{ m/s}^2$).

For the already selected type of servo motor, with corrections of some elements of mechanical transmission (transmission ratio, feed screw lead etc.), we may obtain a higher acceleration of the machine slide using the appropriate optimization procedure.

The acceleration of the machine slide is given as:

$$a = \frac{dv}{dt} \left[ \text{m/s}^2 \right]$$

(25)

For the variant with a ball feed screw and nut:

$$a = \alpha_1 \cdot \frac{h \cdot i}{2\pi} \left[ \text{m/s}^2 \right]$$

(26)

and for the rack and pinion variant:

$$a = \alpha_1 \cdot r_p \cdot i \left[ \text{m/s}^2 \right]$$

(27)

where: $v$ is a rapid traverse feed rate [m/min]; $h$ is a feed screw lead [m]; $r_p$ is a radius of the pinion [m]; $i$ is a transmission ratio; $\alpha_1$ is an angular acceleration of the loaded motor shaft $[\text{rad/s}^2]$. 
The angular acceleration of loaded motor shaft $\alpha_1$ is

$$\alpha_1 = \frac{Ma}{J_{tot}} \text{[rad/s}^2]$$

(28)

where: $Ma$ is an acceleration torque of the selected motor [Nm].

In that case equations (26) and (27) are transformed into:

$$a = \frac{Ma}{J_{tot}} \cdot \frac{h \cdot i}{2\pi} \text{[m/s}^2]$$

(29)

$$a = \frac{Ma}{J_{tot}} \cdot \frac{r_p \cdot i}{\pi} \text{[m/s}^2]$$

(30)

The optimization of a transmission ratio $i$, feed screw lead $h$ or radius of the rack pinion $r_p$ will be done by using the following procedure:

1. For every standard value of the feed screw lead $h$ or radius of the pinion $r_p$ we can calculate the transmission ratio range $i_1 \leq i \leq i_2$, to satisfy the following conditions:
   - the calculated necessary motor speed $n_e$ for the desired rapid traverse feed rate must be smaller or equal to the maximum motor speed $n_m$ ($n_e \leq n_m$),
   - the total load torque $M_{tot}$ must be smaller or equal to the nominal motor torque $M_n$ ($M_{tot} \leq M_n$).

2. In the range $[i_1, i_2]$ we will find the maximum of the function of acceleration $a = f(i)$ at constant $h$ or $r_p$:

$$\max[a(i)] = \max[a(i_1), a(i_2), a(e_1), \ldots, a(e_j)]$$

(31)

where $e_1, \ldots, e_j$ are extremes in the range $[i_1, i_2]$.

The extremes can be found by the equation

$$\frac{da(i)}{di} = 0$$

(32)

The function of the acceleration $a = f(i)$ in the range $[i_1, i_2]$ may have one, more or no extremes (fig.4).

![Possible forms of the function of acceleration](fig.png)

Fig.4: Possible forms of the function of acceleration

When the function of acceleration $a = f(i)$ gets a maximal value for the constant feed screw lead $h$ or radius of the pinion $r_p$, the transmission ratio obtains the relative optimal value $i_{opt}$.

3. To get the absolute optimum of the transmission ratio $i_{opt}$ and optimal values of the feed screw lead $h_{opt}$ or of the pinion radius $r_{p_{opt}}$ we should repeat $n$ times procedures described above in 1 and 2 for all standard values for $h$ and $r_p$. 
and $r_p$. In that way we will get $n$ relative optimal transmission ratios $i_{opi}$ for the appropriate $n$ different standard values for $h_i$ or $r_{pi}$, where $i=1,...,n$.

The pair $(i_{opi},h_i)$ or $(i_{opi},r_{pi})$ that gives the maximal value for the acceleration function, will provide the absolute optimum for the transmission ratio $i_{opt}$, and, the optimal value for the feed screw lead $h_{opt}$ or for the radius of the pinion $r_{opt}$.

It means

$$\max\{a(i_{opt},h)\} = \max\{a(i_{opt1},h_1),...,a(i_{optn},h_n)\} \quad (33)$$

or

$$\max\{a(i_{opt},r)\} = \max\{a(i_{opt1},r_{p1}),...,a(i_{optn},r_{pn})\} \quad (34)$$

Using equations (33) and (34) we obtain the pair $(i_{opt},h_{opt})$ or $(i_{opt},r_{opt})$ which provides a maximal value for the function $a=f(i)$.

This optimization procedure is different from procedures shown in [1,5], where the relative optimal transmission ratio $i_{opt}$ is calculated using equation (32) without taking in consideration $n_e \leq n_m$ and $M_{tot} \leq M_n$.

The theoretical assumptions treated in the text above, are implemented in the computer program, written for PC in C language.

4. SUMMARY

The created computer programs enable an efficient interactive and optimal design and analysis of different variants of CNC machine main spindle and feed drives. The presented software also reduces the design time and modernizes the design process.

ABSTRACT
A high response time to customer requests, plurality of product-variants and a rising pressure of prices are challenges facing businesses in the global-based economy. In particular, the use of integrated software solutions offers here the chance of a competitive advantage by reducing the processing time and increase flexibility in regard to product development. The integration of software solutions for the planning process - Computer Aided Design, Computer Aided Manufacturing, Computer Aided Process Planning - and production - Enterprise Resource Planning - has also in the future great potential to improve flexibility and lower the time to react to customer requests. Related to their specific domain these solutions provide good results. The combination and integration of automated process- and production-planning with a CAD Drawing is necessary, but not established until now. In the various planning stages good solutions are reached, but coherences are not well evaluated and implemented. If an optimized routing should be derived directly and automated from the design of the product you have to use a planning tool which connects the individual parts of computerized planning. Therefore a software is in development, which integrate the described planning tasks and additionally ensure the continuity of production, from design to manufacturing. For the optimization, nature inspired methods - such as Swarm Intelligence, Neural Networks in particular the Growing Neural gas, Genetic algorithms - are used to allow an integrated optimization of process planning. The learning ability of the individual solutions allows creating links between planning levels. The modules are: Generating of process variants, search for the resources needed, considering the utilization of resources identified, evaluation of internal and external interdependence. The aim of this paper is to present this model and include internal and external inter-dependencies in the integrated process- and production-planning software. The novel interaction of the natural inspired methods leads to addressing the topic.

1. INTRODUCTION
The use of integrated software solutions in process- and production-planning offers the chance of a competitive advantage by reducing processing time and increasing flexibility regarding product development. The integration of software solutions for the planning process, Computer Aided Design (CAD), Computer Aided Manufacturing (CAM), Computer Aided Process Planning (CAPP), and production where Enterprise Resource Planning (ERP) is used - has great potentials to improve flexibility and reducing the reaction time to customer requests in the branch of customer-individual manufacturing in the future.

In the various planning stages, good solutions are reached, e.g. CATIA for CAD and SAP for ERP-Systems. But there is no look for the coherences between the various stages. This is one fact for the deficit of these single solutions in the main task of process and production planning. The necessary combination and integration of process- and production planning to the design of a product in its implementation (number one in figure one) are not established until now. Additionally the use of natural inspired methods, such as Swarm Intelligence, Neural Networks in particular the Growing Neural Gas (GNG) or Genetic Algorithms (GA), to allow such an integrated optimization (number two in figure one) is not included.

* Corresponding author: Tel.: +49 (0) 375-5363265; E-mail: daniel.kretz@fh-zwickau.de
Two problem areas have been identified and worked on. First, develop an integrated planning environment for process-planning in product development especially using, second, a novel combination of natural inspired methods for producing the patency of process and production planning.

The starting point for developing the planning environment is a feature-based CAD-Drawing. With this drawing it will be possible to create automatically a working plan. This is performed in compliance with the main criteria of various target areas in the existing contracts of the company and its scheduling (Detailed Scheduling (DS)).

To reach the main targets or coherent targets of the company for example in DS, heuristics, specifically natural inspired methods (Swarm intelligence, neural networks, especially the Growing Neural gas, genetic algorithms) are used.

2. PRESENT SITUATION

Since the early 1950s, the investigations of scheduling problems have been in the focus of Operations Research (OR). However, it is difficult to use OR-results in real production environments. Reasons for this are as follows [13]:

- The many details of the recent application situation (alternate machines, cleaning times, setup time, etc.)
- the dynamic and uncertain structure of the production environment (random disturbances, unpredictable periods of preparation, etc.)
- in generally reluctant optimality criteria
- the need to interact with the user

To handle these and other multi-objective optimization-problems, it should be an advantage to use natural inspired methods or heuristics. A first example therefore is the method of Swarm Intelligence, with the basis of collective behaviour of decentralised systems. Simple agents are interacting between themselves and their environment. An important representative method is imitation of ants at foraging [4], but was initial developed in 1991 by Dorigo [3]. As further developments are the Particle Swarm Optimisation [8], the Fully Informed Particle Swarm [12] or the Rough Particle Swarm Optimization Algorithm [1] to mention. In the field of process-planning not many applications are known.

Another method to solve optimization problems are neural networks. They imitate natural learning models and systems, such as the human brain. The use of neural networks in an automated planning process is elicited and documented many times (e.g.[14] or [11]). Particularly, the Growing Neuronal Gas (GNG), initially described by Fritzke ([6], [7]), is distinguished by its capacity to add new nodes. These approaches consider individual sections of the automatic selection of mechanical resources. But there is no concrete examination of the situation in utilization of the company and no sequence optimization.

Newer approaches automate the planning process by suggesting automatically generated sequences and allocated the necessary resources. Khalifa et al. [9] describes, for example, a neural network, which allows determining the
available machines, tools and their capacitive situation. However, there is no integration of CAD drawings by an automated process planning. The inclusion and/or evaluation of different process variants are not established until now.

Genetic algorithms are heuristics, which imitate the natural evolution in reference to their population. In relation to combinatorial optimization problems in the production, numerous preparatory works are known. Tamura [15] for example uses a GA with heterogeneous population to solve multi-criteria planning-problems. Another Example is Fayad [5] who approximates to an unsure finishing date and those implementation with the aid of GA’s and fuzzy logics.

A simple method in the integrated production process is the repetition of planning (using saved work plans). Variant planning is very sophisticated. On the basis of input of certain work piece data, parameters for specific work plans are generated automatically and combined. In contrast to that procedure, the application of generative computerized work planning in practice is still fairly new. Basically there are four distinguished types of computerized process planning systems:

- variant planning systems
- generative process planning systems
- hybrid theories (combination of variant planning and generative process planning
- knowledge-based methods

The main task of production planning is to schedule processes in relation to the target criteria of the company. Recently, there are increased efforts to integrate the process and production planning and to prepare the continuity between CAD, CAPP, CAM and PPS. Amaitik et al. [2] developed a computerized environment for process planning with the integration of STEP (Standard for the exchange of product model data) AP224-Features. The use of features for process planning is dedicated to Tong et al. [16]. He describes how features are extracted from the neutral STEP AP214 data and implemented into a knowledge-based process planning. Interesting is the approach of Li et al. [10]. They assume flexible process plans which are optimized by genetic programming. This solution will be able to create suggestive process plans, but there is no look for the coherences to the definition in the drawing model.

In the various fields of research different problems are solved and their solution is documented. The integration of product- and process-planning has not been investigated until now. This leads to focus on a planning-environment which unites the various fields.

3. DESCRIPTION OF THE FRAMEWORK

One of the tasks is to study the interactions of different natural inspired methods on the basis of theoretical and practical steps, which should be clarified in the following chapters. Figure two gives an overview about the successive steps for the integration of process- and production-planning.
3.1. GENERATING PROCESS VARIANT PLANS USING SWARM INTELLIGENCE (FIRST STEP)

The basis of the developed software solutions are variants of the process, which are based on a CAD drawing. These variants are created by using natural inspired methods, e.g. swarm intelligence.

The problem of creating a process variant is similar to the travelling-salesman problem without returning to the starting point. All features of the CAD drawing must be attended to describe the product, but not necessarily in fixed order. Geometric and technological restrictions from the features on one hand and from the assigned process-steps on the other hand are necessary for the developed solution. Possible methods to generate the variant plans are for example Ant Colony Optimization or Particle Swarm Optimization.

One focus lies in the problem-specific mathematical formalization of relevant algorithms. As an opening solution, only a small number of useful technological variants are identified. These variants refer to the resources-equipment and their workload in the focused time-horizon. After steps two and three (see chapter 3.2 and 3.3), the target function can be determined.

Based on the best solution or the best solutions of the investigated algorithm with reference to the determined candidates, it is possible to interact with natural inspired methods to develop a certain amount of new solutions. These new solutions influence these steps again and can be assembled with others in process planning. This procedure is repeated and gradually leads to finding a certain (at least local) optimal sufficient solution.

The final output of the selected algorithm in this step is the provision of a technologically sensible, in reference to the target areas optimal variant of the process.

3.2. SEARCHING THE REQUIRED RESOURCES BY NEURAL NETWORKS (SECOND STEP)

After the generation of process variations for manufacturing, possible consequences of the various features of the CAD drawing (such as a sequence of intermediate products) have been created. Now the required resources have to be allocated. This happens on the edges of the process variant. These edges describe the essentially working step and are carriers of production time and costs.

For this assignment, in addition to the consideration of manufacturing features, the upstream and downstream states of the product (intermediate products) are relevant, because a matching of clamping device and work piece, weight, etc. must be made. In addition, the parameters of the features themselves influence the needed resources.
There are high-dimensional vectors on both sides, demand and supply, colliding each other. These vectors need a high dimensional search. Conventional search methods are not applicable here, because it is very difficult to point out the primary parameters. So, multidimensional index-structures are indispensable. A requirement of a feature in the specific context of the preceding intermediate product, the requirement vector, can therefore assign the appropriate resources. In the context of developing a custom procedure for determining the resources it will be an advantage to liberate this from Step 1 and model it as an artificial neural network.

By clustering similar resources it is possible to build competence bundles. A requirement of a feature in concrete context of the precedent intermediate product, the requirement-vector, can be assigned to the suitable resource. To develop a dynamic progress by adding new resources in the company, the GNG is preferred.

In this step it has to be referred to the interdependences which can lead to an increase or decrease of numbers of variants from the first step. For example, it can be possible that one feature will be made by two directly following producing-steps. Another possibility is that two or more features can be made in one producing-step. This case leads to an increase/decrease of features and thereby a increase/decrease of variants. Additional, this has the consequence that step one has to restart. These interdependences have to be described and finally build up in the learning-attitude of the neural network.

The result of this step is the second module of the software solution. The generated variants from step one and the required resources (from this step) are assigned to technological parameters that are necessary for step three.

3.3. Considering the utilization of the resources (third step)

The actual utilization of resources within the company finds the needed consideration in this task. If the company wants to get an assessment of the costs for the production of the component, it is not enough to use a quantitative-time viewing. Rather all existing contracts, a process variant as a result of step 2 and all the machines have to be considered.

This step ends in the valuation of a production variant in context with the utilisation of the company. The use of genetic algorithms proved to be right for machine scheduling and resource assignment in the last years. That is why GA’s are chosen for this step.

Because of the fact that the choices of the parameters and the kind of algorithm have an influence to the needed resources and the convergence of the method, it is necessary to accomplish comprehensive parameter studies. Furthermore, the primary target is to develop a target function of the optimization method. Additional to costs of material and production, it is essential to consider calculated costs for late delivery, non-compliance of price-agreement and image-damage.

From a mathematical point of view this is a multi-objective optimization problem in which the individual optimization goals compete in general, so they are often not complementary or indifferent. For this reason, in most circumstances candidates of solutions cannot be compared directly. Therefore it is necessary to develop a common objective function from the individual targets, e.g. using the AHP (Analytical Hierarchy Process) method.

Another result from this step is the opportunity to re-evaluate the first step with several new candidates of solutions. It is important to guarantee, that no solution will be dominated by another one. A disadvantage of these methods is that the targets should be clarified before running the AHP. But in some cases this will be very speculative for the decision maker.

The aim of the work in Step three is the third module of the software solution which evaluates the process variants with regard to the concrete capacitive situation in the company.
3.4. ELICITING OF INTERNAL AND EXTERNAL INTERDEPENDENCES (FOURTH STEP)

Due to the fact that a combination of these procedures for the integration of process and production planning is new, in this step the main target is to elicit the interdependences of the individual algorithms on practical application, some already described in the steps one to three.

The following interdependences are possible:

- Internal interdependences
  - Temporal dependencies of algorithms, especially for parallelization of the algorithms used in step one and three.
  - Change of the requirement due to structural dependencies of the logical design object.
  - Parametric dependencies of the various algorithms.

- External interdependences
  - Change of the CAD drawing
  - Change of resources structure in the company
  - Lack of resources and allocation of manufacturing steps outwards
  - Change of aim preferences in relation to costs, quality and so on

The goal of this step is to increase the flexibility of the software solution and to advance the predictability of the quality of the solution.

4. CONCLUSION

In this paper four steps are considered. Steps one to three have the aim to investigate, develop and combine the various methods for process and production planning.

For this the first module of the software, described in the first step, is already devised. The current task is to develop modular software which is used for the interaction of natural inspired methods in process planning, described in the second and the third step. This creates a planning system which elicits the interdependences in work plan. It creates an integrative planning environment which produces the continuity of product development.

Step four should elicit the dependences of the individual sections of the continuity software solution and implement obtained cognitions. Important results of the four steps are saved solutions which can derive for the next customer order. So they influence the following passes of the process.

ABSTRACT

The sheet metal industry is very important today and sheet metal components are used in different fields such as Automobile, Aerospace and electricity industry. Application of the progressive die is one of the most important methods to produce sheet metal components, since it reduces production cost and time and increases quality of products. In progressive dies, two or more stations are used. In each station, one or more processes are applied. However, the design and manufacture of these dies are difficult. CAD/CAM systems have been proved to be very useful tools for this task. The main problem of CAD/CAM systems used in progressive die design is determining the operations sequence. In this paper, a system for determining the sequence of the bending and piercing operations is described. In this system, piercing and bending operation are separated and the sequencing of each type is done individually. For piercing stations, Fuzzy set theory is applied and the sequencing is done in one stage. For bending operations sequencing is done in two stages. First, the bending operations, which can be carried out simultaneously, are defined by a classification method. The sequence of the bending operation groups is then determined using fuzzy set theory. The capabilities of the system are shown using a sheet metal component.

1. INTRODUCTION

Progressive dies are used to transform flat strips of sheet metal into a formed part. This transformation is performed progressively by a series of stations that cut, punch, form, and bend the material into a desired shape. A progressive die that performs the various forming operations on the material is unique for every part. The various components that make up the die are located in guided and precision cut openings in plates, which are in turn located and guided by pins. The entire die is actuated by a mechanical press that moves the die up and down, and the sheet metal is fed through the die progressing from one station to the next. Progressive die design is a relatively complex and highly iterative process. Today's progressive die manufacturers face a number of issues that hold back improvements in productivity, quality, and turnaround time. These range from a lack of experienced progressive die designers, the difficulties involved in speeding up and improving quality in the more traditional design methods, and a shortage of any specific, easy-to-use, productive software solutions for progressive die design. In order to maintain their competitive edge and survive, more and more progressive die companies are looking to adopt three-dimensional computer aided design (3D CAD) technology and using computerized system for die progressive design.

2. RELATED WORKS

Researchers have tried for many years to develop a computerized system to design and manufacture progressive dies. In 1971, Shaffer [1] developed a Progressive Die Design by Computer (PDDC) system and Fogg and Jaimson [2] followed him by developing an improved PDDC by considering other factors which have an effect on die design. A weak point of this system is that it is semi-automated and the processing time is too long. Shibata and Kunimoto [3] developed a CAD/CAM system for which the aim is the screen-output of blank layout and die layout. Nakahara et al introduced a system of a progressive die design [4]. Choi et al. [5] developed a compact and practical CAD system for the blanking or piercing of irregular shaped sheet metal...
products and stator and rotor parts. Nee et al. [6] developed a computerized system to design and production of piercing progressive dies. Nee and et al. [7] used fuzzy set theory to determine bending sequencing. Kim et al. [8] developed a CAD system for the blanking and bending operation in sheet metal products. They used fuzzy logic in their system. They used 3 rules for piercing operations and 6 rules for bending operations sequencing. Farsi et al. [9] developed a new method to determine bending sequencing in progressive dies. Their algorithm was based on classification and fuzzy set theory.

These systems are mostly used as an assistant for the progressive die designer. Often, these systems have been focused on one operation type: bending or piercing operations. The number of the stations suggested by these systems is often more than the actual industrial parts. So the die layout suggested by these systems is usually modified manually by the designer. Also, the systems mostly recognize features interactively and feature recognizing is done using 2-D model or wire frame.

In this paper, a computerized system is described. This system is used for designing progressive die layout. This system includes feature extractor, manufacturability check and layout design modules. Features are recognized automatically from a solid model and the features are controlled using design for manufacturability considerations. At the end, using sequencing operations algorithms layout is designed and the sheet metal shape in each station is presented as 3-D model.

3. STRUCTURE OF THE SYSTEM

The system includes input and shape definition, Design For Manufacturability (DFM) and station layout design modules. Figure 1 shows the configuration of the system. This system developed in solidworks environment using Visual Basic (VB). The system recognizes sheet metal features and their data are saved in a file. These data are used to control production feasibility. Then features are separated to bending feature and piercing features. In the system first piercing operations and then bending operations are performed. The functional description of the system modules are presented in detail as follows:

![Figure 1. System configuration](image)

3.1. INPUT AND SHAPE DEFINITION MODULE

The features that are basic to sheet metal parts are stamped and formed features. Stamped features are categorized as internal and external features. Internal features include features like round holes, square holes, rectangular holes, oblong holes, etc. External stamped features include different types of notches. The most widely formed features are bends and flanges.

In the feature recognition module, all data used for the system are extracted. These data are used for DFM check, flating of the part and sequencing. Data modeling methodology in this work is based on object oriented approach. For example, the following data are extracted from a bend feature:

- Bend radius
- Bend angle
- Length of each bend
- Bend height
- Bending direction (up/down bending)
Coordination of start, end and middle points on bend line
Connected planes to bend
Bend factor (it is used for unfolding calculations)
Material thickness

3.2. DESIGN FOR MANUFACTURABILITY MODULE

The sheet metal industry is largely an empirical industry. The design and process planning of sheet metal products need human involvement more than other areas of manufacturing industry. Design of complex parts are based heavily on human experience. In the design stage, if some of the design considerations are ignored, the cost of production may increase rapidly. There for in this system a DFM module is provided and the system can control feasibility of sheet metal component by design considerations rules. These rules were saved in a data base. DFM rules were extracted from metal forming fundamentals, Industry observation, Hand Books, DFM books. All of the features recognized by input and shape definition module can be checked in this module. In the next paragraphs, some of the design rules are discussed. For more information see ref. [10].

a. Holes: The diameter of punched holes should be greater than the thickness of the work piece and not less than 2.5 mm. This is because the punch diameter becomes too small to bear the shear force required to punch the hole over a small area, often leading to failure.

Oblong holes: Oblong holes are generally incorporated as adjustment slots. As a general rule, the length to width ratio of an adjustment slot should be no more than 5 to 1.

b. Notches: Notches should extend inside the stock edge at least 1.5 times the thickness but not less than 0.50 mm. The minimum widths of tabs and slots should be 1.5 times the thickness or 0.5 mm. Their length should be a maximum of 5 times their width.

c. Bends: The width along the bend axis should be greater than or equal to 3 times the thickness. The bend radius \( R_b \), \( R_b \geq C \times t \) (t denotes the component thickness and C is a coefficient and depends on the material type).

d. Slot: The minimum widths of tabs and slots should be 1.5 times the thickness or 0.5 mm. Their length should be a maximum of 5 times their width.

3.3. STATION LAYOUT MODULE

This module is a computer aided process planning module to determine operations sequencing. Determination of operations sequence is the main problem in progressive die design. This problem is more important when the part has bends features. If \( N \) is the number of bending operations in a given part, then the domain of possible sequences in principle is \( 2N! \) [11]. Also, if \( M \) is the number of piercing operations, then the domain of possible sequences in principle is \( M! \). If the bending and piercing operations are performed separately then the total domain of possible sequences is \( M! + 2NN! \).

However, this number is usually limited due to geometrical and technical constraints. In other words, the number of possible sequences depends on the shape of the component. In this module, first the mother plane is determined. Then operations sequence is determined. At the end, the system presents the die stations layout as 2-D and 3-D model.

4. OPERATIONS SEQUENCING

Operations sequence is the most important and complex stage in a sheet metal component die design system. The system has to determine mother plane of the component and then determine sequencing of the operations using special algorithms.

4.1 MOTHER PLANE

Mother plane has a very important role in bending progressive die design. The mother plane is a fixed plane which stays without any rotations throughout the bending operations. All the rotating planes are called children planes. The rules for the determination of mother planes are as follows:

A plane surrounded by other planes
A plane located in the center of the part
The largest plane in the component
Figure 2 shows the mother plane for the sample part, the mother plane is colored in this figure. When the determination of the mother plane is not clear from the conditions as stated above, it is determined by the minimum number of bends between a plane and the plane in the central plane.

5. PROCESS PLANNING RULES FOR PIERCING OPERATIONS

The rules and the database of process variables are derived from plasticity theories, relevant references and the empirical know-how of experts in the blanking or piercing industries. The fuzzy set theory constructs a fuzzy matrix for calculating fuzzy relationship values and determines the optimum sequence by combining several rules with fuzzy reasoning.

Rule 1: Relation rule
Two types of relations among piercing features is-in and is-along are represented in the relation rule. Holes and slots in the plane are defined as the “is-in” relation; and notching, and piercing of the outer feature along the plane as the “is-along” relation. The fuzzy membership function of this rule is shown in Figure 3a.

Rule 2: Force and Shear length rule
One of the most important problems in the progressive die design is the forces and moment equilibrium. This affects the die lifetime and if the forces and moment are in equilibrium state then the lifetime is longer. The piercing force depends on the size of shear length of the shape to be pierced. Therefore, some of the die designers suggest which the piercing operation with larger force is performed in middle section of die. In other word, the smaller shapes are performed earlier. The fuzzy membership function of this rule is shown in Figure 3b.

Rule 3: Adjacent piercing rule
This rule is applied to adjacent shapes to be pierced so that the piercing is possible with a single punch shape, and the fuzzy membership function is shown in Figure 3c.

6. BENDING OPERATIONS SEQUENCING

In this system, bending sequencing is done in two stages. First, the bending operations, which can be carried out simultaneously, are defined by a classification method. In this method, all the bends are initially divided according to their bending directions (feed direction or perpendicular to it). Then for each direction, the bends are divided into operation groups according to classification rules. Three rules are used to determine the bending operation groups in this paper. These rules are based on relations between the bends in the component. The sequence of the bending operation groups is then determined using fuzzy set theory.

6.1 BENDING CLASSIFICATION METHOD
The classification technique is applied to the determination of simultaneous bends which can be performed in one station. The die designers use different rules to define simultaneous bends, because several parameters affect this procedure. According to experimental studies, many factors affect the determination of the simultaneous bends. However, the following rules can be summarized [9].

**Rule 1:** The bends that have bend lines along one line and whose bending directions are the same (up or down bending) can be performed in one station. Thus, they are said to be in one group.

**Rule 2:** The bends that have parallel bending lines and their bending directions are the same (up or down bending) and are placed on opposite sides of the mother plane can be performed in one station and are said to be in one group if the number of the planes between them and the mother plane are equal.

**Rule 3:** Related bends. In some sheet metal components, two planes can be related through geometric or dimensional tolerances. To obtain the tolerance and to comply with the positioning errors, these bends should be (or better be) performed together.

### 6.2 Fuzzy Set Theory

The handling rules and criteria needed for determining the bending sequence is discussed in this section. These rules deal with the selection of the next best bend for the bending operation. Each of these rules establishes relationships between pairs of bending operation groups. A high membership grade indicated for a particular rule means that the bend group is a good selection for the next operation according to this rule. These relationships between the bending and criteria are represented as fuzzy relations, and the membership grades of these fuzzy relations are determined through fuzzy membership function, as shown in Figure 4.

Fuzzy relations or sequencing rules describe the priority of each group. Thus, definition of these rules for a computer aided system is important. According to previous studies and experience of the authors, the following rules are suggested:

**Rule 1:** Distance rule. This rule describes the influence of the shape of a bend on the sequencing strategy. The further a bend is away from the mother plane, the higher its grade will be and thus should be bent earlier. The fuzzy functions presented in Figure 4a are used to determine the grade of membership by this rule.

**Rule 2:** Number of bends in a group. The higher the number of bends in a group, the more impact it will have on the overall shape of the part and vice versa. The more impact a group will have, the later it should be addressed in the operation. So the fuzzy relationship value of this rule can be represented as in Figure 4b.

**Rule 3:** Bending angle. This rule is to determine the fuzzy relationship value according to the angle of each plane. This is the angle between the mother plane and each rotated plane. If this angle is greater than 90°, the bending process is divided into one or more processes. The fuzzy relationship value is unity in the case of a bend angle less than 90° and zero in other cases. These relationships according to bend angles are represented as fuzzy functions as shown in Figure 4c.

**Rule 4:** Feeding direction. This rule is to determine the fuzzy relationship value of a fuzzy function according to whether or not the bend is in the feeding direction. After bending, an escape space is necessary in either the stripper plate of the upper die or the die plate of the lower die. The escape space should be at a minimum considering the die strength, the part to be fixed, the loss of die material, and the manufacturing time. Bending processes requiring a large escape space should be performed later to minimize the escape space. Because a bend perpendicular to the feeding direction requires a smaller escape space than a bend in the feeding direction, the former precedes the latter. The membership value for the perpendicular feeding direction is unity, and zero otherwise. The fuzzy membership function for this rule is shown in Figure 4d.

Note: To determine the grade of the membership for each group, the maximum grade of its bends is chosen and later used in the fuzzy matrix.

![Distance Rule](a.png)  ![Number of bends in a group](b.png)
Let $C=\{c_i\mid i=1, 2, \ldots, n\}$ represent the set consisting of all the remaining piercing operations or bend classes that are being considered for bending, where $c_i$ is one of the bend classes or piercing operations.

Let $R=\{r_j\mid j=1, 2, 3, 4\}$ represent the set of four criteria in the handling rules for bending or three rules in piercing operations sequencing, where $r_j$ represents one of the criteria.

A fuzzy relation is a mapping from $C \times R$ into $[0, 1]$, such that $(V_{ij})$, is expressed as follows:

$$(V_{ij}) = f(c_i, r_j)$$

Since related sets $C$ and $R$ are finite, a fuzzy relation $f$ on $C \times R$ can be represented as a fuzzy matrix $[M]$, the entries of which are $(V_{ij})$.

The determination of the grade, which may vary anywhere between zero and unity, is based on the sequencing rules. The fuzzy matrix $[M]$ for bending classes is shown in Table 1.

### 7.2 Determination of Final Value Matrix (FVM) set

FVM is a matrix consisting of fuzzy values for each bend groups or piercing operations that are being considered. The fuzzy values are determined by implementing rules described in sections 5 and 6.2. These rules have been found to give suitable results in piercing and bending operations. The higher value an operation has, the sooner it should be performed. The relative importance of the rules is represented as a fuzzy set $W[R]$, as shown in equation 2 for the piercing operations and equation 3 for the bend groups.

$$W_{p}[R] = \{\eta_1 * 2.0, \eta_2 * 1.5, \eta_3 * 1.0\}$$

$$W_{b}[R] = \{\eta_1 * 1.2, \eta_2 * 0.8, \eta_3 * 0.6, \eta_4 * 0.2\}$$

Thus, the FVM set can be expressed as in equation 4:

$$FVM(C) = [V], W_{c/b}[R]$$

### 8. Die Layout Design

After the determining of operations sequence, the system determines number of the die stations and specifies which operations are performed in each station. According to these results, the system presents die stations layout as 2-D and 3-D model. User can interactively change operations sequence and add idle stations to suggested layout, if the proposed sequence is not suitable. At the end, the system presents the final layout. In part II of the paper, the system capabilities are explained using two sheet metal components.
9. EXAMPLE

Figure 5 shows a part used in automotive industry (Iran Khodro Company). This part has eight bends with several internal and external stamping features. When a component requiring piercing and intricate bending operations is applied to the system, the study considers the results carried out in each module.

9.1. INPUT AND SHAPE DEFINITION MODULE

The system automatically recognizes all of features such as bends, holes and notches. In this module first, material type and the thickness of component is extracted. Then bends and piercing features are recognized. Figure 6 shows bends parameters for this part extracted by the system. These parameters include radius, angle and length of each bend and their connecting planes. Other parameters of the bend feature such as bending direction, coordination of the start and end points are extracted too. According to bends lines vectors, the system suggests component arrangement on the strip.

Metal that is rolled shows grains along the direction in which the stock was drawn through the mill rolls. Bends should be at right angles to the grains or as close as possible to avoid breakage of the blank. So bends in each direction are calculated and the system suggests suitable feeding direction according to material type and number of bends in each direction. User can modified the components arrangement on the strip and change that. Figure 7 shows schematic of the part arrangement on the strip suggested by the system for this component and feeding direction according to arrangement. Optional arrangement which can be selected by user is shown too.

9.2. DESIGN FOR MANUFACTURING MODULE

The advisory system uses features data extracted in the recognition module. In the following some of the advisory system outputs are described. Figure 8 shows the slot features are not correct and the circle radius is
small. Also, the bends radiuses are small. These features are highlighted by red color and should be changed by the user. For example in the mother plane of the part, D-shape piercing feature is correct. The distances between features are enough and more than 2 times the thickness. But the diameter of the hole is less than 2.5 mm and the length to width ratio of the slots are more than 5 to 1 ratio. But in this example the ratio is 6.5. Also, according to material type (Hardened Low carbon steel) minimum radius of the bends is 6 mm. In the first step, the system highlights incorrect features and then the advisory module's comments are presented to the user.

Figure 8. Features checked by DFM rules

9.3 STRIP LAYOUT MODULE

In this module first, the mother plane is determined (it is highlighted in figure 5) and the flat view of part is created (Figure 9). Then in the sequencing stage, piercing and bending operations sequence are determined. This part has six internal piercing operations and eight external piercing (notches) operations. To separate the part from the strip, four cutting operations are used. Separating operations are defined interactively and ignored in the system.

Figure 9. Piercing and bending operations

According to sequencing procedure, first piercing operations are sequenced using fuzzy rules. Table 2 shows the results of fuzzy matrix and FVM for piercing operations.

According to table 2, number of the piercing stations is 9. Piercing operation C4 is punched in the first station and piercing operations N4 and N5 are performed in the last station.

Bending operations are sequenced in two stages first, they are classified and then the bending classes are sequenced by fuzzy logic.

According to the classification rules, the classes of this part are determined as follows:
- Bends B1 and B5 are in class 1, according to rule 2.
- Bends B2 and B6 are in class 2, according to rule 2.
- Bends B3 and B7 are in class 3, according to rule 2.
- Bends B4 and B8 are in class 4, according to rule 1.

After the classification of the bending operations is determined, the sequence of the operations can now be determined according to the fuzzy matrix as shown in table 3.

According to table 3, number of the bending stations is 4. Bends B3 and B7 are performed in the first station and bending B1 and B5 are performed in the fourth station of the bending stations. Figure 10 shows the suggested die layout for this part. In this figure, some of the piercing stations are not shown, because if all stations are shown, figure quality would be reduced.

If this layout is compared with the die layout used in industry [12], it can be seen that the proposed bending operations sequence is similar to industrial die, but the number of proposed piercing stations is more than that. Thus piercing operations sequence should be changed by user. The user can change and modify the system output in system edit menu. He can add operational or idle station to die layout.

According to the number of piercing stations, in next study authors try to develop and improve the sequencing method for the piercing operations.
10. SUMMARY

In this paper a new system for the determination of bending and piercing sequences for progressive dies is described. The system includes three modules as follow: Input and shape definition, design for manufacturing, stations layout. In this system, sheet metal components are modeled using solidworks and their features data are extracted. Then features are controlled by DFM rules. In next step, operations are sequenced and 2-D and 3-D layout of the die stations are presented. In this system, first piercing operations and then bending operations are determined. Fuzzy set theory are used to determine piercing operations sequence, but determination of bending operations sequence are done in two stage; First the bends are classified then the bends classes are sequenced using fuzzy set theory. After sequencing, the system presents the part in each bending stations as 3-D model and die stations layout as 2-D and 3-D. The suggested layout can be modified interactively if it is not suitable.

ABSTRACT

This work proposes and implements a group of procedures to integrate physically and logically a group of CNC machines, an industrial robot and an automated storage and retrieval system (AS/RS) into a Flexible Manufacturing Cell (FMC). Initially, the modeling of the FMC was carried out, based on the definition of a group of minimum interfaces for each piece of equipment, through the use of Petri Nets. After modeling the cell, an integration model was implemented, based on management modules developed using a supervision and control software (Elipse SCADA). Each module was conceived with enough interfaces to allow the integration of different manufacturers' equipments, which provides flexibility to the configuration of the cell. The communication among the several modules is accomplished using the OPC (OLE for Process Control) technology, which enables the data exchange among managers in real time and in an open way. The integration between the managers and their respective pieces of equipment is made through PLCs (Programmable Logic Controllers). The system allows the manufacturing simulation of a family of parts, without the interference of machine operators. Human-Machine Interfaces (HMI) were developed to allow local and remote users (i.e. physically distant) to input and monitor their production orders in the cell.

1. INTRODUCTION

Manufacturing has been affected by profound changes in the last decades. The globalized competition, together with the increasing demand for product innovations, personalized products, high quality, and lower prices, force the companies to modernize their production methods. Changes used to be implemented as a means to provide a distinguishing characteristic to a company in relation to another, but now they are made as a survival factor in an uncompromising and competitive market. The distinguished technological characteristic that some corporations had in the past, which allowed the production of certain products with unique features, is becoming increasingly rare today. In the past, the consumer had to adapt to products supplied by the companies, but today the companies need to understand and adapt to the consumers' demands.

Manufacturing systems that prioritize production volume, with low cost and small variety, are facing the challenge to increase the flexibility of production and to diversify their products, and at the same time to decrease costs. For small and medium production batches, Flexible Manufacturing Cells (FMC) and Flexible Manufacturing Systems (FMS) are viable alternatives to respond to the challenges of flexibility, variety and reduced costs.

The concept of FMS involves a high degree of automation, where manufacturing is accomplished through automated machining centres, and the transfer among the machines is done by automated conveyor belts or automated guided vehicles. Positioning and motion of the parts are accomplished by robots. The raw material and the finished products are stored at an automated storage and retrieval system. The resources are linked to a computer system that coordinates all the actions, enabling the system to produce different types of parts. The technical complexity and the high acquisition costs and implantation of FMSs hinder its use significantly in companies and education and research institutions.

There are nowadays two possible solutions for the installation of a FMC or a FMS. The first of them is to acquire a turn-key solution supplied by companies such as Yamazaki Mazak [1], Kearney & Trecker [2], Heller [3], among others. In this case, technology transfer to the user does not usually happen, because the systems are

* Corresponding author: Tel.: +(55)(48) 3721-9387 ext 212; Fax: +(55)(48) 3721-7615; E-mail: jcarlos@emc.ufsc.br
not open. The second option is to build a FMC or FMS with the physical and logical integration of a group of pieces of equipment for processing, handling, transporting, and storage. In the latter case it is necessary to define a group of interfaces for the machines, to model the manufacturing system, to establish an integration pattern for the heterogeneous equipments, a communication pattern, a control system and a computer system that manages the whole structure and provides means to interface with the user. This work describes the integration of machines in a FMC in the latter approach, by applying a modular, open and expandable philosophy, in such a way that the FMC can manufacture different parts in an autonomous way.

2. EQUIPMENT IN THE FMC AND INTEGRATION ARCHITECTURE

The equipment used for the development of this work is located at Sociedade Educacional de Santa Catarina (SOCIESC) in Joinville, Brazil. It is composed of one CNC machining centre, one CNC lathe, an industrial robot, and an automated storage and retrieval system (AS/RS). Figure 1 shows a partial view of the machines being integrated. The computer resources are composed by two PLCs and six computers, all interconnected through an Ethernet network.

![Figure 1: Partial view of the machines being integrated in the FMC](image)

One of the most difficult problems to form a FMC consists of integrating different pieces of equipment, manufactured by different suppliers. Individually these machines present few communication resources with the outside environment. The robot, the CNC machines and the AS/RS have different hardware and no communication pattern. This work proposes the implementation of an open system, in which the different manufacturing resources are represented by modules, with a minimum group of interfaces. Managers are built to command the actions of the modules, in order to exchange data amongst themselves through an open standard for industrial communication, and that does not require the use of non-standard protocols.

The supervision and control software Elipse SCADA [4] will be used to build the managers, one for each resource in the cell. PLCs will make the connection among the managers and CNCs, which have only one serial port (RS232) for receiving the machining programs (G codes). The robot, which is equipped with a Profibus standard communication card, uses this resource to communicate with a PLC that is connected to the manager. The AS/RS has a human-machine interface (HMI) that is modified to accomplish the manager role. Figure 2 presents the proposed architecture for integrating the cell.

Besides the managers that correspond to the machines present in the cell, two other managers will be developed, with the objective of providing an interface with the users. One of them (FMC manager) should allow the local user to input his/her manufacturing orders, and to provide the user with all the information about the status of the machines, status of the manufacturing orders, to print reports, and to inform about any alarms. The second manager (remote manager) has the function of allowing an user who is physically distant from the cell to input his/her manufacturing orders.

3. INTERFACES

To accomplish the integration of the FMC, it is necessary initially that the different machines exchange data amongst themselves. The strategy used for interconnecting the pieces of equipment was the construction of one manager for each of them, using the Elipse SCADA supervision software. The different managers exchange messages using an Ethernet network. Each manager exchanges information with its respective equipment through PLCs.
To begin modelling the cell it is necessary to define the possible events, the hierarchy of the control system, and the minimum number of necessary messages to synchronize the actions in FMC. The definition of the necessary messages for modelling the cell is based on the combination of two main topics. Firstly, the choice of the control architecture that seeks to decentralize the decision process, increasing the autonomy of the system. All the managers built for integrating the cell act on the same level and in a cooperative way. The second point refers to the use of modular control through Discrete Events Systems (DESs), which allows complex problems to be decomposed into simpler modules, and then later the solutions are set up in a modular structure.

Torrico and Cury [5] proposed a model based on a modular hierarchical supervision control through state aggregation, where the hierarchy is divided into two levels: a level associated with the operator, and another level associated with manager. The application of this architecture allows a consistent and non-blocking behavior between the hierarchy levels, and the combined action of the several managers in the lower level. This model is applied in this work, where the level associated with the manager is represented by the equipment manager and the set of conditions and rules that compose the decision process. The second level is associated with the operator, and is composed by the execution elements, which are responsible for the effective integration between the managers and the pieces of equipment, accomplished through PLCs.

3.1. INTERFACES OF THE CNC MACHINES

The robot is responsible for loading and unloading the parts in the CNC lathe, CNC machining centre, and the CNC R1 (hypothetical third CNC machine). The cell manager is responsible for informing each CNC machine about which NC program (G code) should be loaded. There is no exchange of information between the AS/RS and the CNC machines.

After decomposing all of the possible actions of the CNC machines, and considering that each module manager should have the greatest possible autonomy, the interfaces were determined.

The CNCs should receive the information regarding which NC programs should be executed from the cell manager. The information on the robot states are supplied directly by the robot manager, and they indicate whether the robot is free or in some loading or unloading procedure, or if it placed or removed some part from the fixturing device of the CNC machines, and if the robot is within an area considered safe for the CNC machines to operate, avoiding the risk of collision. The information that the CNCs should supply the cell manager and the robot manager are basically to indicate whether the CNC machine is free or executing a machining process, if the door is open or closed, and if the fixturing device (three-jaw chuck, vice, collet, etc.) is open or closed.

With these defined and standardized interfaces, different CNC machines can be included in the FMC, provided they are physically within the robot workspace.

3.2. INTERFACES OF THE ROBOT

Still applying the philosophy of decomposing the robot actions in the FMC, and considering that the robot moves the parts between the AS/RS and the CNC machines, the group of interfaces can be defined. All the CNC machines (i.e. lathe, machining centre, and CNC R1) should provide the robot with indications whether they are idle or machining, the condition of their doors, and their fixtures. The AS/RS informs the robot about the presence of parts to be machined in the “mesa1” (table1) or in the “mesa2” (table2) of the machining cradles. The FMC manager should indicate which program the robot should execute.
The robot needs to inform its condition (idle or in loading movement), the position for loading or unloading the fixturing devices of the CNC machines, the retrieval or storage of parts in the pallet on mesa1 or mesa2 of the machining cradles, the presence within the area considered as safe for operation, and the condition of operational abnormality or emergency.

With these interfaces, the robot is capable of supplying and receiving the necessary information to load the appropriate programs and to synchronize all the events of material manipulation in the FMC.

3.3. INTERFACES OF THE AUTOMATED STORAGE AND RETRIEVAL SYSTEM

The AS/RS is initially responsible for supplying the raw material to be processed. After the machining, the AS/RS can store the finished product or to move it to the exit conveyor, for subsequent transport and delivery to the final customer. The AS/RS receives information from the FMC and robot managers. The FMC manager provides the information regarding which parts were selected for machining, the amount and the destination of the products already processed, as well as the strategy of movement of the transelevator. The return of the parts, coming from the CNC machines, to the mesa1 or mesa2, is signalled by the robot.

The information that the AS/RS needs to make available to the system is: (a) the pallet arrival with parts to be processed in the mesa1 or mesa2 of the machining cradles, and (b) the messages about the internal states of the AS/RS and the transelevator.

Besides the interfaces described above, there are others associated with the AS/RS, such as the entry and the storage of raw material. These interfaces are not analyzed based on the possible actions of the AS/RS, because they are not essential for the synchronism and integration of the cell. Those interfaces are responsible for the exchange of data between the AS/RS manager and its database, i.e., they are information treated in an autonomous way by the AS/RS manager, reducing significantly the traffic of messages among the different managers in the cell.

3.4. INTERFACES OF THE FMC MANAGER

The FMC manager has the primary function of serving as interface with the local and remote operator, allowing them to: input manufacturing orders, indicate the movement strategy, priority, amount, etc. Also, the manager should monitor the main events associated with the equipments in the cell, in order to determine and to communicate the choice of the NC programs and the robot programs. Hierarchically the FMC manager is on the same level as the other managers in the cell.

4. DISCRETE EVENT MODELING THROUGH PETRI NETS

In order to model a FMC, different tools can be used, among them the Finite Automata and Petri Nets [6]. According to Mušic and Matko [7], one of the greatest problems in the use of automata for developing the structure of supervision and control systems in real industrial processes, is the explosion of states. Thus, Petri Nets (PN) are advantageous, especially with regard to the possibility of modelling the aspects related to the synchronization and the non-determinism of the execution, or parallelism, and for presenting an additional information structure that reduces the problem of the explosion of states [8].

In this work, PN were used to model the FMC. One of the reasons for this choice is that PN describe in details the characteristics of the necessary conditions to trigger each transition, and the execution of the necessary actions to operate the system. This description of conditions and actions are transposed in an almost literal way for the generation of the supervision and control codes in the Elipse SCADA software, facilitating the construction of the managers extremely.

Figure 3 presents the PN structure that models and interprets the movement of the raw material from mesa1 of the machining cradle to the CNC lathe. The places represent the states of the resources; the transitions model the sequence of actions (events) that modify the resource states; the arcs represent the flow of the process; the tokens indicate that the predicate associated with the place is true. The return of the part already processed by the lathe to the present pallet in mesa1 is described by other PN. That PN is composed of 12 places, 9 transitions, and 16 variables.

5. CONVERSION OF THE IPN TO SUPERVISION CONTROL CODES

From the cell model using IPN (Interpreted Petri Net), the trigger conditions of each transition and the actions resulting from triggering can be directly translated to programming scripts of the Elipse SCADA software. The variables used in the modelling that indicate the conditions and the actions associated with each transition are already in the format of tags.
Implementation of a Modular Supervision System for a Flexible Manufacturing Cell

Figure 3: Simplified IPN for moving parts from table1 to the CNC lathe

Ellipse SCADA is an event-oriented software, which means that the execution of any programming script depends directly on the occurrence of a discrete phenomenon. This characteristic is used as trigger condition of each transition in the cell model. The programming script, always associate with an event, contains the codes that represent the actions to be executed by the system. The control of the evolution of the states in the supervising system is centred on the events that trigger the transitions. Figure 4 presents an example of the conversion of the IPN model for generating the supervision controls, and they represent the update of the NC programs in the cell, triggered by the arrival of a pallet in mesa1 of the machining cradles of the AS/RS (OnValueChanged event - it triggers whenever its value changes).

6. MANAGERS OF THE STORAGE SYSTEM AND THE FMC

The implementation of the different managers proposed in this work was done similarly, and therefore this paper describes the implementation of the managers of the AS/RS and the FMC. It is intended to build these managers within a single application, unifying the input and output interfaces. Initially, the conversion to tags is carried out, which is the first step for constructing the application.

The AS/RS manager should command the following actions: entry of the pallet containing raw material or finished parts, storage of pallets, transportation of parts to the machining cradles, return of the parts from the machining cradles, and pallets retrieval. The intervention of an operator consists of loading the material on the pallets and their placement on the entry conveyor. This task can also be accomplished by an AGV, and the application of the AS/RS includes this condition, but it will not be used in the present implementation because the laboratory does not have an AGV. When accomplishing the entry of a raw material in the AS/RS, the operator needs to inform a code that refers to the material type to be stored. These codes are previously registered in the manager's database, as well as the machining code, which needs a corresponding raw material and a pre-determined machining table. The database used is Microsoft Access.

To order the production of a part, the user should input the code of the part, in order to indicate the amount of parts to be produced, where the part will be moved to after the return from usinagem, and the priority of the operation (normal or urgent).

The tag “MovPeca” (move part), belonging to the AS/RS manager, is associated with an object type Setpoint, where the user types in the code of the part to be machined. When the user presses the Confirm key, the content of the MovPeca tag is copied to several tables of the database. When the task is executed, and the pallet arrives at one of the tables of the machining cradles, the tag “ProgUsinagem” (machining program) is attributed the value of the MovPeca tag, through a reading of the database. The box “Saida” (exit) indicates that the pallet will be moved to the exit cradle, and not to the storage shelves, after the machining process is completed. Figure 5 shows the script associated with the tag “presenca_mesa1” (present on table 1), triggered by the arrival of the pallet in mesa1, associated with the OnValueChanged event. This script updates the ProgUsinagem tag that will be read by all the pieces of equipment in the cell through OPC (OLE for Process Control) communication standard. Depending on the reading of this tag, the robot manager will load the movement program “m1f1” (from table 1 to machining centre 1), and the machining centre will also load the corresponding machining program.
Figure 4: Example of conversion of IPN into control code

Figure 5: Script associated with the presence_table1 tag
The instruction of the script "ProgUsinagem=tab05_usinagem.produto" is responsible for updating the ProgUsinagem tag from "tab05_usinagem", "product" column in the database. The machining table in the database is used by the AS/RS manager to rank machining tasks. The user can input several machining orders at the same time, and each order will be inserted in the list of tasks in the database. The process of updating the ProgUsinagem tag, from the machining table, enables the synchronization of the robot movement and the load of the program in the CNCs with the arrival of the pallet containing the raw material in the machining tables. The tag “código_retorno_M1” (code for returning M1) receives a numeric value that indicates the CNC machine from which the part will return to mesa1, and the phase of the process in which the part is. The first digit indicates the CNC that is processing the order (lathe=1, machining centre=2, and CNC R1=3). If the second digit is equal to zero, it means that the part is being load in the CNC machine.

After updating the ProgUsinagem tag, caused by the arrival of the pallet in mesa1, the robot executes the program m1f1, and moves the raw material to the machining centre. When the machining of the part begins, the ProgUsinagem tag should be updated immediately, otherwise the program containing the motion of the robot would repeat the initial request. To accomplish this function, the closing of the door of the machining centre (which starts the machining cycle) is used to update the ProgUsinagem tag. In this way, when the robot returns for “Phome”, it will be capable of executing a new requested movement.

The AS/RS manager, as well as the FMC manager, needs many pieces of information about the other managers, as defined by their interfaces. Figure 6 shows the structure of the OPC servers in the organizer of the application and in one of the screens of the FMC manager.

Figure 6: Structures of the OPC servers and a screen capture of the FMC manager

The Manager screen provides the user with a summary of the states of the resources in the cell. The information about the CNC machines, the robot, and of the remote manager is obtained from OPC servers. On the other hand, the information about the AS/RS is directly linked to the tags of the AS/RS manager. The OPC tags are decomposed through scripts and organized in a group of tags ("Pulgus"), which contains the following groups of secondary tags: Auxiliaries, CNC R1, Machining Centre, Robot, and Lathe.

7. GENERAL INTEGRATION OF THE FMC

In this combination of the managers of the manufacturing resources with the FMC manager and the remote manager, all of the managers are connected through a local Ethernet network, and each manager carries out the OPC server and client roles at the same time. When an application supplies information to other managers, it is an OPC server, but when it receives data from another manager, it behaves as an OPC client.

Several versions of the Windows operating system were used in the managers (e.g. NT, 2000, XP-HOME and XP-SP2), which executed in several computers, with Pentium 200 MMX to Pentium 4 2.8 MHz processors. All the computers have Ethernet cards, and those that communicate with PLCs have at least a RS232 serial port, except the FMC/AS-RS manager, which has two serial ports (one used to communicate with the master PLC Moeller, and other with the bar code scanners of the pallets). The robot controller has a Profibus network card (DSQC 352 model), used to communicate with the Siemens PLC.
After integrating the managers, the FMC is capable of producing the parts previously registered in the database of the FMC/AS-RS manager. To begin the operation of the system, it is necessary that all the managers are in operation, the communication network is active, and all the pieces of equipment and PLCs have their programs loaded.

The user interface with the FMC is the FMC/AS-RS manager. In this HMI the user registers the parts and processes, inputs the entry and exit of raw material in the AS/RS, and requests the production of the parts previously registered in the system. The access of the user to the manager is accomplished through password, for safety reasons. The FMC/AS-RS manager also allows monitoring the main events and states of the manufacturing resources in the cell, to emit reports on produced and stored parts, and to find stored raw material and finished parts.

The ABB robot, model IRB 2400/10, has a claw for manipulating and transporting materials between the AS/RS and the CNC machines, and vice-versa. Any other robot type can be used in the cell, as long as its workspace reaches the tables of the cradles of the AS/RS and the CNC machines. Also, it should have an appropriate claw for manipulating and transporting materials in the cell, and its controller should have sufficient capacity for programming and communication with the external environment.

The used CNC machines, a Feeler FTC10 lathe and a Feeler FV-600 machining centre, demanded hardware and software adaptations for proper integration in a FMC. The necessary alterations encompass the automation of the doors and fixtures, besides the reservation of a group of internal memories to indicate the download of the NC machining programs. Other CNC makes and models can be used in FMC.

To include a new CNC machine in the cell, it is not necessary to alter the model of the cell, being enough to build a new manager similar to the lathe, machining centre, and R1 managers. Also, the programs for moving the robot should be generated for tending the new CNC machine, and the programming scripts associated with the OPC tags should be altered.

In the case of including a measurement equipment, which could be a laser micrometer, it would be necessary to define a group of interfaces for building the new manager. In this case, once again it would not be necessary to model the cell. The robot movement would have to be altered to take the part to the measurement system. If the part is approved, the robot would move the part back to the pallet. In case of rejection, the robot would move the part to a reject or rework buffer.

8. CONCLUSIONS

This work aimed at providing a guideline for constructing a FMC through the physical and logical integration of heterogeneous pieces of equipment, and we consider that this objective was reached. The proposal encompasses the modelling of the system using Interpreted Petri-Nets, the specification of a set of interfaces for each equipment, the construction of managers based on a SCADA supervision software, the integration of the managers with CNC machines and robot using PLCs, and the integration of the managers through the OPC industrial communication standard.

As future works, it is necessary to develop a new FMC manager, using the Elipse E3 supervision software, which enables to incorporate all the managers developed with Elipse SCADA, besides making it possible the remote operation of the FMC through the Internet.

Cooperative robot kinematics to perform load sharing tasks

Cristiane P. Tonetto¹ and Altamir Dias

ABSTRACT

This paper presents a research of robot's cooperation applied to load sharing tasks, by using non usual techniques such as Kirchhoff-Davies method, Assur virtual chains and screw theory. Many robotics applications are currently being restricted by the fact that there are limits in the performance of tasks by a single robot. One example of such restriction is when it is necessary to move one object from a point to another and it is very heavy or extremely big to be done by only one robot. In this case, two or three robots are needed in order to achieve the task. So, the paper focus will be centered in the description of the task trajectory on the operational space, and how to synchronize and establish the cooperation between two or more robots, by using non usual techniques. It explores some procedures to describe how the robots can move over the trajectories needed complying with the task(s) parameters. By using the screw theory it is possible to know and to control the relative movements between all the manipulators links. A procedure based on the Kirchhoff-Davies method is used to establish the instant speeds between joints from the desired speeds/positions on the robots workspace, thus being possible to solve the inverse kinematics of the robots. The kinematic chain of the robots is considered as closed chains, so additional auxiliary virtual chains are added to the system in order to close opened chains. Virtual chains, also known as Assur virtual chains, are used to define desired characteristics or constraints on the movements to be performed by the robots, besides being used to couple the robots movement. All the trajectory planning is intended to be planned off-line. Although this approach is new and uncommon on the current literature, the final results are very good and compatible with the results of other techniques. Finally, a simulation sample of robots performing tasks on the operational space is presented.

1. INTRODUCTION

Due to the ever growing request for industrial products and thus higher production, robots are more and more commonly used in the industry. Eventually the need to use many robots cooperatively emerges, such as in part handling and load sharing operations. A cooperative robots system is defined as a system composed by several robot manipulators, acting collectively in order to perform one or more tasks. So, to program cooperative robots it is necessary to know how to generate automatically the robots program to different configurations, what is its geometry and how to give the task specifications. Some authors have researched the use of more than one robot performing tasks, such as Lewis [1] and Owen, Croft and Benhabib [2], which assume the whole system as a single redundant robot and the way to plan trajectory for two robots; Dourado [3] researches the kinematic and trajectory planning for planar cooperative robots and Ribeiro, Guenther and Martins [4] propose a Cooperation Jacobian for cooperative robots.

This paper intends to present some basic tools used on the robots kinematics computation and further describes the procedure to compute kinematics of two cooperating robots performing tasks such as the load sharing tasks.

2. TOOLS FOR ROBOT’S KINEMATICS COMPUTATION

The differential kinematics relates the joint speeds to the end effector’s, and can be represented, for example, as a Jacobian matrix (J) that is a function of the current configuration of the robotic manipulator. The Jacobian for serial

Flexible Automation and Intelligent Manufacturing, FAIM2009, Teesside, UK

manipulators is usually attained by using one of two methods: one based on the Denavit-Hartenberg convention and other on the screw theory [5].

This paper uses the screw theory approach, as it is a new methodology, successfully used on several robotics researches, such as on the UFSC robotics group. On the other side, the Denavit-Hartenberg is well known and yet widely used on robotics researches.

2.1. SCREW THEORY

The Chasles’ theorem establishes that the displacement of a rigid body can be represented as a rotation around a fixed axis and a translation in the direction of the same axis. The combination of the translation and rotation movements is called screw displacement [6]. As the screw displacement can represent both rotation and prismatic displacements, it is possible to represent two different types of joints that define the relative displacements of links in a single way, so being possible to overcome pose questions in a generalized way.

Figure 1 depicts the screw displacement of a point $P$ on the space from the $P_1$ to the position $P_2$. These displacements can be represented by a rotation of an angle of $\theta$ over the screw axis followed by a translation of $t$ on the same axis. The vector $p_i$ denotes the initial position of the point $P$ referenced to the coordinate’s system $O$, the vectors $r_1$ and $r_2$ are same size vectors that define the initial and final position of $P$ according to the screw displacement. The $p_f$ denotes the position of $P$ after the translation, according to the reference system $O$ [6].

![Figure 1: Displacement of the point $P$ on space](image)

On a system where many rigid bodies are displaced, the $s_i$ vector denotes the unitary vector that defines the direction of rotation and translation of the screw axis, so that $i$ refers to the index of the link or fixed body. The $s_{oi}$ vector denotes the $s_i$ vector of the position according to a fixed coordinate system of a reference link. The angle $\theta$ is the rotation angle of the $P$ point and $t$ is the length of the displacement of the translation of $P$ [6,7]. For convenience, the vectors $s_i$ and $s_{oi}$ shall be chosen perpendicular, that is:

$$s_i^T \cdot s = 0 \quad (1)$$

The Mozzi theorem states that the speed of the points of a rigid body relative to a reference system $O(x,y,z)$ can be represented by a differential rotation around a fixed axis and a simultaneous differential translation on the same axis [5]. Thus, any movement of a rigid body can be considered a screw displacement.

To take in account that the instantaneous movement of a rigid body relative to a inertial system is composed by a pair of vectors $(\omega, v_p)^T$. So, $\omega=(\omega_x, \omega_y, \omega_z)$ denotes the angular speed of a body relative to the chosen coordinate system and the vector $v_p=(v_{px}, v_{py}, v_{pz})$ represents the linear speed of a point $P$ that is in the body [5].

Once more, the instantaneous movement can be decomposed as an amplitude and a normalized axis, when there is only rotational or translational movement. When the move is a rotation, the amplitude is the magnitude of the angular velocity $||\omega||$, and when the move is a translation, the amplitude is the magnitude of the linear velocity $||v_p||$. 

Page 131
A screw $\hat{s}$ is the geometric element defined by a directed line on the space and by a scalar parameter $h$ of length unit that defines the pitch. The normalized screw $\hat{s}$ of a joint $i$ is given by:

$$\hat{s} = \begin{bmatrix} s_i \\ s_o \times s_i + h \cdot s_i \end{bmatrix}$$  \hspace{1cm} (2)$$

where $h$ is the screw pitch and $s_o \times s_i$ is the vector product between $s_o$ and $s_i$ vectors.

It is possible to verify that when the rotation movement is around the $s_i$ axis and the translation over the $s_i$ axis, the screw represents the instantaneous movement:

$$\hat{s} = (\omega, v_p) = \hat{s} \cdot \dot{q}$$  \hspace{1cm} (3)$$

The screw can define the differential displacement between two bodies according to a reference coordinate system. The differential kinematics between two links of a given kinematic chain is generally defined by one revolute or translational joint. In the case of different types of joints, such as spherical joints, they can be decomposed in three different revolute joints.

When the movement is related to a revolute joint, there is no translation, that is, the pitch of the screw is null ($h=0$), and the screw displacement is given by the equation:

$$\hat{s} = \begin{bmatrix} s_i \\ s_o \times s_i \end{bmatrix}$$  \hspace{1cm} (4)$$

In the case of a prismatic joint, there is no rotation movement ($\theta=0$), only translative, so the pitch of the screw is infinite ($h=\infty$), and the screw displacement is given by:

$$\hat{s} = \begin{bmatrix} 0 \\ s_i \end{bmatrix}$$  \hspace{1cm} (5)$$

The resulting screw of the displacement of the end effector can be given by adding the screws of each one of the joints, that is:

$$\hat{s}_E = \sum_{i=1}^{n} \hat{s}_i \cdot \dot{q}_i$$  \hspace{1cm} (6)$$

where $\hat{s}_i$ is the $i^{th}$ normalized screw described in relation to the reference coordinate system, $\dot{q}_i$ is the magnitude of the displacement of the rigid body $i$ and $\hat{s}_E$ is the resulting screw that represents the end effector movement according to the reference coordinate system. Then the displacements of the joints represented by normalized screws and their magnitudes are computed [6].

### 2.2. Kirchhoff-Davies Method

The Kirchhoff mesh rule establishes that the algebraic sum of all potential differences on a closed electric circuit equals null. Davies adapted this mesh rule for mechanism kinematics computation on closed kinematic chains, so that the sum of relative speeds between two adjacent links throughout any kinematic chain is null. This is known as the Kirchhoff-Davies method, and it become possible to establish an instantaneous relationship between the speeds of all joints of a closed kinematic chain using the speeds representation instead of screws. This relation is named equation of manipulators kinematic chain constraint [3,5,7].

The application of the Kirchhoff-Davies method is better understood with an example with a $n$ bars and $n$ joints mechanism (Figure 2). So, suppose that the screw $\hat{s}_A$ represents the movement of link 2 related to the link 1, thus, the screw $\hat{s}_i$ represents the movement of the link $s_{i+1}$ related to the $i$ link, so that $1 < i < n$. The screws $\hat{s}_A, \hat{s}_B, \hat{s}_C ... \hat{s}_n$ represent the kinematics pairs $A, B, C, ... n$, respectively.
The link 2 motion related to link 1 is represented by the screw $S_A$, and the link 3 movement related to link 1 is represented by the algebraic sum of the screws $S_A + S_B$. As the link 1 is fixed to the ground its motion related to itself is null and can be written, as shown in the equation (7), applying the Kirchoff-Davies method for closed chains.

$$S_A + S_B + S_C + ... + S_n = \vec{0} \quad (7)$$

The $\vec{0}$ vector is a vector of (3×1) dimension. Changing its screws to its normalized axis $\hat{S}$ and by the speed magnitude $i_q$ leads to:

$$\hat{S}_A \hat{q}_A + \hat{S}_B \hat{q}_B + \hat{S}_C \hat{q}_C + \cdots + \hat{S}_n \hat{q}_n = \vec{0} \quad (8)$$

where $\hat{S}$ represents the normalized screw of the screw $S_i$ and $\hat{q}_i$ represents the magnitude of the speed related to the $i$ joint, so that $i \in \{A, B, C, ..., n\}$.

The matrix format is:

$$\begin{bmatrix} \hat{S}_A & \hat{S}_B & \hat{S}_C & \cdots & \hat{S}_n \end{bmatrix}_{3 \times 4} \begin{bmatrix} q_A & q_B & q_C & \cdots & q_n \end{bmatrix}_{4 \times 1} = \vec{0} \quad (9)$$

And generally, the constraint equation is:

$$N \dot{q} = \vec{0} \quad (10)$$

The equation (10) can be rewritten in order to find a way to solve the differential kinematics on the joint space of the kinematic chain and this way finding the speed magnitudes of the passive joints as a function of the actuated joints. The matrices of equation (10) can be divided in two different groups: the joints with known speed magnitudes (primary joints) and on the ones with unknown magnitudes (secondary joints), that is:

$$\dot{q} = \begin{bmatrix} \dot{q}_s & \vdots & \dot{q}_p \end{bmatrix}^T \quad (11)$$

Reassembling the $N$ matrix according to the magnitudes leads to:

$$N = \begin{bmatrix} N_s & \vdots & N_p \end{bmatrix} \quad (12)$$

Finally resulting on equation (13):

$$\begin{bmatrix} N_s & \vdots & N_p \end{bmatrix} \begin{bmatrix} \dot{q}_s & \vdots & \dot{q}_p \end{bmatrix}^T = \vec{0} \quad (13)$$

Setting the matrices apart produces equation (14):
Cooperative robot kinematics to perform load sharing tasks

\[ N_s \dot{q}_s = -N_p \dot{q}_p \tag{14} \]

And thus, equation (9) can be rewritten to:

\[ \begin{bmatrix} \hat{S}_{m+1} & \hat{S}_{m+2} & \cdots & \hat{S}_s \end{bmatrix} \begin{bmatrix} q_{m+1} & q_{m+2} & \cdots & q_s \end{bmatrix}^T = -\begin{bmatrix} \hat{S}_p & \hat{S}_q & \cdots & \hat{S}_n \end{bmatrix} \begin{bmatrix} \dot{q}_p & \dot{q}_q & \cdots & \dot{q}_n \end{bmatrix}^T \tag{15} \]

where \( m \) is the number of primary joints.

If \( N_s \) is invertible, the speed magnitudes of the secondary joints \( \dot{q}_s \) can be computed by the following equation:

\[ \dot{q}_s = -N_s^{-1} \cdot N_p \dot{q}_p \tag{16} \]

2.3. ASSUR VIRTUAL CHAINS

The Assur virtual chains were developed in order to help the application of Kirchoff-Davies method. An Assur virtual chain is a serial kinematic chain with virtual links and joints [5]. It must comply with certain properties, so that the virtual joints movements are represented by linear independent screws and a virtual chain cannot change the degree of freedom of a real kinematic chain.

Therefore, in order to use a kinematic chain, a serial chain must be defined, and it must have the same degree of freedom of the screw system in which the real kinematic chain is presented.

As the kinematic chains are modified by the added virtual kinematic chains without changing the original chains mobility, it is possible to get information and introduce characteristics on its movement, making possible the application of closed chains algorithms in open chains.

The virtual kinematic chains can be classified according to the screw system order \( \lambda \) in which the real kinematic chain is included. If the real kinematic chain is planar, the screw system has \( \lambda=3 \) and if the real kinematic chain is spatial the screw system has \( \lambda=6 \). The planar virtual chains can be PPR with two prismatic and one revolute joint or RPR with one prismatic and two revolute joints. The spatial virtual chains can be PPcP with three prismatic and one spherical joint, RPPs with one revolute, two prismatic and one spherical joint [5].

The definition of which virtual joints to choose depends over the desired characteristics of movement, defined by the space over which the trajectory will be defined. In spatial virtual kinematic chains, the order of the screw system is \( \lambda=6 \), and thus the virtual chain have a degree of freedom of six. The spherical joints can be swapped by three orthogonal revolute joints.

3. IMPLEMENTATION

In order to verify the described theory, two cooperative anthropomorphic robots were simulated, in a load sharing task, following circular trajectories. The size of the links, types of joints or robot model, the relative distance between robots and initial pose of the robots are considered inputs for the problem. From the robots model or links size it is possible to find all the values of \( s \) and \( s_o \) and to find the robot screws and to apply the Kirchoff-Davies method to compute the inverse kinematics.

It will be used two similar anthropomorphic robots, with spherical wrist (according to model in Figure 3). This robot has six revolute joints and its end effector has to follow the trajectory \( x=1,81+\cos(t), y=sin(t) \) and \( z=3,77 \) with \( 0 \leq t \leq 2\pi \). The initial configuration of each of the first robot joints are: \( \theta_1=0, \theta_2=7\pi/10, \theta_3=-\pi/2, \theta_4=-\pi/3, \theta_5=0 \) and \( \theta_6=0 \). The end effector of second robot must follow the movements of the first, so that the relative movement between the first and the second robot remains null. The initial configuration of the second robot is: \( \theta_7=\pi, \theta_8=7\pi/10, \theta_9=-\pi/2, \theta_10=-\pi/3, \theta_11=0 \) and \( \theta_{12}=0 \).
In order to find the values of $s_a$ and $s_o$, the reference position of the robot is considered (Figure 3b). As the planning is made off-line, the reference position can be any desired position, so it was chosen a position in which the robot was horizontally so that it is possible to visualize $s$ and $s_o$ vectors. The position of $s_o$ can be any point over the screw axis, and thus for convenience, it is chosen the point that lies over the robots joint. After that, the correct homogeneous transformations are applied over $s$ and $s_o$, in order to get the values of $s$ and $s_o$ of the manipulator in any configuration besides the reference position.

The values of $s$ and $s_o$ for the first stretched anthropomorphic manipulator are described on Table 1, the joints of the real manipulator are numbered from 1 to 6.

<table>

In order to compute the values of $s$ and $s_o$ from the data of the stretched manipulator an algorithm was implemented. This algorithm applies the homogeneous transformations over $s$ and $s_o$ for each joint recursively. Thus it is possible to have the values of $s$ and $s_o$ for each one of the special manipulators joints, in a generic way, as a function of the joints angles. On the implemented algorithm the resulting $s$ and $s_o$ vectors are a function of the angles $\theta$, that is, a function of the joint angles. The values of $s$ and $s_o$ that result from the application of the algorithm for the first manipulator, are given on the Tables 3 and 4.
Table 3: Values of \( s \) for the first manipulator.

The Figure 4 shows a robot and the virtual chain used in the computation of the kinematics using the Kirchhoff-Davies method. It is considered that a 3P3R virtual chain links the manipulators base with the end effector, and the chain compounded by the end effector and the robot is closed and the Kirchhoff-Davies method can be applied.

Figure 4: Circuit that represents two collaborating manipulators
From the circuit it is possible to find the $N$ matrix:

$$
N = \begin{bmatrix}
    \dot{s}_1 & \dot{s}_2 & \dot{s}_3 & \dot{s}_4 & \dot{s}_5 & \dot{s}_6 & -\dot{s}_{p1} & -\dot{s}_{p1} & -\dot{s}_{p1} & -\dot{s}_{p1} & -\dot{s}_{R1} & -\dot{s}_{R1} & -\dot{s}_{R1} & \ldots \\
    0 & 0 & 0 & 0 & 0 & 0 & \dot{s}_{p1} & \dot{s}_{p1} & \dot{s}_{p1} & \dot{s}_{p1} & \dot{s}_{R1} & \dot{s}_{R1} & \dot{s}_{R1} & \ldots \\
    \ldots & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
    \ldots & \dot{s}_{p2} & \dot{s}_{p2} & \dot{s}_{R2} & \dot{s}_{R2} & \dot{s}_{R2} & -\dot{s}_7 & -\dot{s}_8 & -\dot{s}_9 & -\dot{s}_{p10} & -\dot{s}_{11} & -\dot{s}_{12} \\
\end{bmatrix}
$$

(17)

The $N$ matrix can be decomposed in $N_s$ and $N_p$:

$$
N_s = \begin{bmatrix}
    \dot{s}_1 & \dot{s}_2 & \dot{s}_3 & \dot{s}_4 & \dot{s}_5 & \dot{s}_6 & 0 & 0 & 0 & 0 & 0 & 0 \\
    0 & 0 & 0 & 0 & 0 & 0 & -\dot{s}_7 & -\dot{s}_8 & -\dot{s}_9 & -\dot{s}_{10} & -\dot{s}_{11} & -\dot{s}_{12} \\
\end{bmatrix}
$$

(18)

$$
N_p = \begin{bmatrix}
    -\dot{s}_{p1} & -\dot{s}_{p1} & -\dot{s}_{p1} & -\dot{s}_{p1} & -\dot{s}_{R1} & -\dot{s}_{R1} & 0 & 0 & 0 & 0 & 0 & 0 \\
    \dot{s}_{p1} & \dot{s}_{p1} & \dot{s}_{p1} & \dot{s}_{p1} & \dot{s}_{R1} & \dot{s}_{R1} & \dot{s}_{R1} & \dot{s}_{R1} & \dot{s}_{p2} & \dot{s}_{p2} & \dot{s}_{R2} & \dot{s}_{R2} \\
\end{bmatrix}
$$

(19)

The joints speeds are given by the equation:

$$
\dot{q}_s = -N_s^{-1}N_p \dot{q}_p
$$

(20)

Figure 5 depicts the simulated robots performing the task, with many joints position drawn. Only the manipulator on the left receives the trajectory and the right robot follows the movement, starting from another position over the piece, simulating a load sharing task, so that every robot grabs on a different place of the piece and movement the piece cooperatively. The implementation of the algorithm was executed in Octave [8]. The output of the software is the trajectory of the joints of both robots and the input, besides the robots data, is the desired trajectory defined as the primary joints $\dot{q}_p$ of the virtual chains:

$$
\dot{q}_p = \begin{bmatrix}
    -\sin(t) & \cos(t) & 0 & 0 & 0 & 0; & 0 & 0 & 0 & 0 & 0 & 0 \\
\end{bmatrix}^T
$$

(21)

Figure 5: Two robots in cooperation

So, the trajectory programming is performed automatically, for the first robot by the reference path and for the second robot as null reference, defining that, according to the manipulated object, the end effector of the second robot must remain static. In order to comply with the circuit, the movement of the second robot is automatically computed, as a function of the movement of the first one, thus showing the need of cooperative work.
4. SUMMARY

The application of the described methods, as the screw theory, Kirchhoff-Davies, Assur virtual chains, allows the solution of the cooperation problem in a compact and simple way. The screw theory is able to model in a general way prismatic and revolute joints and operate over them, as illustrated by the spatial example for two anthropomorphic robots. The model of virtual chains is very flexible and allows the robot programmer to define the virtual chains that bests represent the input data. It is possible, for example, to use such concepts to model other kind of restrictions, such as the collision avoidance, as virtual chains. But it is object of research for future articles.

ABSTRACT

This work examines a robot cell consisting of a press brake and a robot which handles the sheet metal, thus replacing the human operator. The motion of both robot and press-brake ram is simulated in a CAD environment enhanced, first, with software simulating sheet bending kinematics and, second, with a genetic algorithm determining optimum bending sequence, both developed in previous research stages. The corresponding robot motion steps are configured following a task-based approach. They are defined parametrically in such a manner as to draw up relatively simple trajectories involving, typically, no more than three joints simultaneously. The range of applications involves variable part dimensions of the final part and of the initial sheet profile. The user is actively involved in several phases of the whole process, e.g. in determining the grasping point of the sheet, in requesting collision detection when required, in modifying robot path when necessary, etc. The methodology and tools developed constitute a good experimentation base towards the ultimate total replacement of the human by the robot.

1. INTRODUCTION

Automated handling in manufacturing processes may use hardware such as robotic arms and software such as CAD-based programs and model-based calculation/decision making algorithms. Very often automation requires both hardware and software in conjunction, e.g. in path planning of robotic manipulators serving machine tools, which is the domain of interest of the current work.

Among the multitude of relevant examples, an approach in robot path planning with collision avoidance, combining end effector motion planning and joints motion planning is described in [1]. A method for the use of robotic fingers in the manipulation of cartons (modelled as kinematic mechanisms) for folding operations in packaging industry is proposed in [2]. Virtual Reality (VR) software is used for modelling robotic manufacturing cells in the early design stages [3]. An analysis of robotic painting for parts with free form surfaces is presented in [4] using CAD-based software taking into account paint thickness. Robot path planning in automotive industry is dealt with in [5], using constraints on robot poses. A more generic constraint-based path planning methodology in a CAD environment is presented in [6] and demonstrated in robotic loading/unloading of a turning center.

Intelligent decisions on robotic path planning may be based on fuzzy logic [7] and on genetic algorithms [8]. Most relevant to the current work, robot path planning software is presented in [9] based on an evolutionary algorithm which decides the most appropriate path of the robot end-effector loading, holding in position and unloading sheet metal part on a press-brake. An initial path is programmed by the user programs and automated evolution of the paths follows in real time in a machine learning approach presented in [10]. The use of neural networks in real time robot path planning in dynamic environments with collision check is analyzed in [11].

In this work, robot path planning is based on robot task analysis and consequent determination of ‘standard’ robot poses. Transition between the latter is implemented with as few simultaneous joint motions as possible, in order to simplify inverse kinematics. Parametric definition of CAD models of the press-brake, handling robot and peripheral devices as well as kinematic analysis capability are the enabling technologies.

2. Problem Definition

For each product that requires a number of bends, the manufacturing process on a press-brake is similar. For the first bend to be executed, the planar sheet metal is moved from a feeding device to the press-brake properly oriented. Before the next bend the sheet metal is moved out of the machine, its orientation is changed and it is positioned between the upper and lower rams. This cycle is repeated until all bends have taken place. After the last bend, the sheet metal part is moved to the output buffer and a new planar sheet metal is loaded. The main constituents of a typical robotic bending cell are: the press-brake, the part feeder and the robotic arm with the appropriate end effector, see Figure 1.

![Figure 1: The robotic bending cell parts (a) press-brake (b) part feeder (c) robotic arm and (d) end effector.](image)

As far as the press-brake is concerned, there is no need for a detailed specification of it and therefore a simple representation with the basic parameters is used. Only some basic dimensions need to be defined along with the orientation and distance from ground level of the bending line. Besides, the whole process task analysis is designed so as only few basic movements take place near the press-brake, in such a way that the details of the press-brake design do not interfere with the robot motion; this facilitates replacement of the press-brake by another design.

The part feeder is designed to hold in place the planar sheet metal with defined orientation and position. Moreover, it keeps constant the distance of the sheet metal to be loaded from the ground level. It can be used for a variety of products and their corresponding initial sheet profiles.

The robotic arm is one with six rotation joints, providing the ability to place the sheet metal part in any position and with any orientation in the working space of the arm. In addition, the speed and displacement specifications of the joints have been taken into consideration for the simulation process. In task analysis no more than three joints work together for each time motion step, which simplifies robotic programming within similar applications (e.g. same product family, only dimension differences, etc.)

The end effector is designed to be a hybrid magnetic/vacuum effector that can handle both metallic and non-metallic sheet materials. Its basic dimensions are also taken into consideration in the simulation process keeping in mind the variety of parts that can be handled.

The parts are placed in clearly defined positions in the bending cell, that have been chosen in such a way that the needed manipulations are reduced and/or simplified as far as possible. Moreover, it takes into consideration that all parts have to be inside the effective working volume of the robotic arm.

The shape of the planar sheet metal and of the final product are analysed to determine specific patches. The main patch is defined as the one that is not rotated during the bending process; it is usually surrounded by other patches, it is in the center of the sheet and/or is the biggest patch. Every patch that is rotated during the process is a secondary patch. When this definition does not suffice, the main patch is defined as the one with the least number of bends joining it with the patch that is located in the center of the sheet. Every patch containing an edge of the initial sheet profile is defined as a simple patch. An example is shown in Figure 2. The grasping point of the sheet is selected as the geometric centre of the main patch. The side of the grasping point may change during the bends depending on the required orientation.
3. BENDING PROCESS PLANNING AND SIMULATION

Before the robot motion simulation, it is required that the position and orientation of the robot end effector is clearly defined for each step of the simulation. The robot end effector is tied to the main patch of the sheet at the grasping point for most of the steps. The steps that correspond to bending stages are excluded, because the robotic arm releases the sheet before these start. In summary, the position and orientation of the sheet must be known for the complete simulation process. Position and orientation is mainly determined by the bending sequence [12]. Software based on genetic algorithms, developed in [13], was used to determine bending sequence in 3D space. The necessary bending process simulation software was also developed.

Bending sequence was determined in previous work using a genetic algorithm for the 2D problem (“paperclip problem”) [12], and evolved next in a fully functional bending sequence optimiser for the real 3D problem [13] which is used in this work. As far as the genetic algorithm is concerned, the software is very similar to the one for the 2D problem described in [12], the chromosome representing a possible bending sequence. For n bends, each individual of the chromosome contains all the bends and each bend just once: [ID₁ ID₂ ID₃ … IDₙ], where IDᵢ is the identification number of bend i. The genetic algorithm creates the initial population, evaluates the fitness function for each individual, uses the genetic operators to create the next population and repeats the process until a certain criterion is reached. The user can change parameters such as population size, number of generations, operator influence, etc.

The difference between the 2D and the 3D problem is in the simulation of the process which is used to evaluate the fitness function. The 3D problem not only involves collision checks and tool changes, but also different types of orientation change. In addition, in the simulation process, a decision making option has been added to determine the best machine stopper position for each bend to reduce dimension faults caused by machine inaccuracy. The tools used are omitted from the chromosome to reduce calculation time [12]. Besides, the tool used is changed only if collision occurs or the user pre-defines a certain tool for a certain bend [13].

Process simulation is used in the genetic algorithm to evaluate the fitness function for each individual, e.g. mainly to determine collisions. It is also used after the determination of the bending sequence for the calculation of the position and orientation of the grasping point of the sheet at the end of each step. The user enters geometry of the initial sheet profile in the form of a complex matrix, each sub-matrix containing the geometry of every patch of the initial sheet profile. Then, each bend that takes place is defined by the patches the delimit it, as well as by bending angle and pre-defined tool used. The algorithm simulates the movement of the sheet as bending takes place, with a step defined by the user; usually 10° are enough for most problems. For each of these discreet angles collisions are automatically determined between tool-sheet, machine-sheet and different parts of the sheet, see Figure 3.
4. Handling Steps

The whole process of robotic handling of the sheet is separated into handling steps, see Figure 4. These steps are simple in that they usually require no more than three joints to be simultaneously active for the corresponding motion to be executed. Moreover, the trajectory in each of these steps is parametrically defined so as to be easy to change from one product to another. For each step, with the use of the process planning and simulation software presented in section 3, the initial and final position and orientation of the grasping point and corresponding patch respectively are known for each step. These delimit the trajectory of the end effector for each corresponding step. The robot motion between these delimiting pairs is defined using simple constraints, such as planar movement, rotation about an axis in 3D space etc. The user can change the grasping point side of the patch if needed during the process; in general, robot movement planning is an interactive process, controlled by the user.

In addition, the user can check for collision between the robotic arm and the press-brake if this is necessary using the corresponding functionality of the CAD modelling environment in which the whole process is modelled. The specific option is not default as it is time-consuming. Besides, there are relatively few ambiguous cases, for which such a collision check is meaningful. The use of the process simulation software, see section 3, already involves a collision check between the sheet and the various parts of the machine, resulting in a collision-free bending sequence. Therefore, this type of collision does not need to be checked in the simulation of the robotic arm movement.

Figure 5 shows the initial and final robot pose for each of these steps (the final pose of one step is the initial one for the next step). Some of these steps may be omitted depending on the part to be handled.

![Figure 4: Definition of robotic handling steps.](image-url)
5. ROBOT SIMULATION

The robot is simulated in a CAD environment, in this case Solidworks™ enhanced with kinematics analysis. In order to exploit in-built kinematics functions in an interactive way, the user instructs the joints of the robot to attain specific positions, corresponding to the robot pose at the end of each handling step. Joint positions are calculated using a simplified inverse kinematics model of the robot. The most complex trajectory involves end effector movement on a specific plane surface by using just three robot joints.

All other movements are simpler, involving one or two joints. In addition, for this type of movement, if one joint is used for the correction of the orientation and the remaining two for the movement of the end effector, the analysis is further simplified.

More specifically, the movement described is that of a virtual robotic arm of two joints in plane $x_0O_0y_0$ as shown in Figure 6, where $l_i$ the length of link $i$, $q_i$ the rotation of joint $i$, $(p_x,p_y)$ the position and $\theta$ the orientation of the end effector. The calculation is shown in the Appendix.
6. CASE STUDY

In Figure 7 a sample final part and its initial sheet profile are shown. In addition, the grasping point is chosen as the geometric center of the main patch.

The bending sequence determined by the genetic algorithm is 3 4 5 1 2. Using the process simulation algorithm, the user calculates the initial and final position and orientation of the grasping point and then with the use of the robot kinematic model, calculates the rotation of each joint for every step. In Figure 8, one particular step is shown for the first bend. In Figure 9 joint angular displacement is depicted for that step involving joints 2, 3 and 5.
7. CONCLUSIONS AND FUTURE WORK

The main idea that was introduced in this work in order to program robotic movements in replacement of the human operator of a CNC press brake is to break down the whole handling process into steps, each of which is simple enough to be performed by simultaneous movement of one to three robot joints. This, first, simplifies the inverse kinematics model that underlies these movements and, second, enables easy modification of each step trajectory to accommodate changes in product shape and size and the corresponding changes in number of bends. So, robustness is achieved at the expense of possibly lengthier paths.

This kind of ‘standardisation’ of robotic handling steps requires a process plan expressed as a series of positions and orientations of the product undergoing bending in consecutive stages. An advanced optimal process plan generator module was used for this purpose, ensuring collision avoidance of the sheet as well as maximum dimensional accuracy of the product.

A stand-alone graphics supported simulator of the bending steps and corresponding configurations of the product was also used in order to determine the position and orientation of the handling tool (robot end-effector) at the end of bending steps which coincide with the start of respective handling steps.

Robotic moves are defined interactively by the user in a CAD environment based on the information furnished by the process simulator and the handling steps definitions flowchart. Any modern CAD environment provides kinematics and collision detection functionality which are necessary in this interactive task.

Parts of the robot programming process can be automated, the main obstacle currently being the decisions to be made as to modifications of the handling roadmap in cases where collisions are found as a result of following some handling step ‘by the book’ when some of the explicit or implicit constraints associated with it are violated. Further work is under way in this direction.

REFERENCES

APPENDIX

\[ p_x = l_1 \cdot \cos(q_1) + l_2 \cdot \cos(q_1 + q_2) \]
\[ p_y = l_1 \cdot \sin(q_1) + l_2 \cdot \sin(q_1 + q_2) \]
\[ \theta = q_1 + q_2 \]

Moreover:

\[ ((p_x)^2 + (p_y)^2) = l_1^2 + l_2^2 + 2l_1l_2c_{q_1+q_2} + l_2^2s_{q_1} - 2l_1l_2s_{q_1+q_2} \Rightarrow \]
\[ ((p_x)^2 + (p_y)^2) = l_1^2 + l_2^2 + 2l_1l_2c_{q_1+q_2} + s_{q_1}s_{q_2} \Rightarrow \]
\[ q_2 = \pm \arccos \left( \frac{(p_x)^2 + (p_y)^2 - l_1^2 - l_2^2}{2l_1l_2} \right) \]

As for \( q_1 \), after some mathematical manipulation, the :

\[ q_1 = \arctan \left( \frac{p_y}{p_x} \right) - \arcsin \left( \frac{l_2s_{q_1}}{\sqrt{(p_x)^2 + (p_y)^2}} \right) \]

where \( c_i = \cos(q_i) \), \( s_i = \sin(q_i) \), \( c_{ij} = \cos(q_i + q_j) \) and \( s_{ij} = \sin(q_i + q_j) \).
THE DIGITAL FACTORY CONCEPT FROM MANUFACTURING TO SERVICES ENVIRONMENT

ABSTRACT

To significantly reduce development time and costs, concurrent work and change iterations (in reverse engineering approach) between design and manufacturing need to be evaluated and managed in near real time. Layout, workspace assessment and procedures, process analysis and validation can be analysed through the integration of multi-objective mathematical procedures, discrete event simulated environment and digital models (i.e., Digital Factory - DF approach). Across a digital world is possible to visualize and bear out and interplay all elements of the “future” growing factory/environment. Furthermore, brainstorms can be found on visual manifestation of hypothetical virtual environments. Expert analyst, from different fields and knowledge (like engineers and doctors), can eventually cooperate and meditate about optimization of procedures and processes on such a digital model. What is more is the possibility of resolving all design mistakes in a fictitious world (i.e., Virtual Reality environment). This significantly reduces the cumulative cost of change and time-to-market while improving quality of supply services.

In this paper, a Digital Factory approach was implemented to analyze and optimize manufacturing as well as services environment. A continuous loop between virtualization and optimization has been engaged. The carried out cases study are the muffler assembly station of an Italian automotive company and the Emergency Department behaviour of an Ireland hospital. The visualization step was, in both cases, the system validation and the final optimization phase of a more complex discrete event simulated environment. Numerical outcomes of the DF approach will be manifested. The outputs will be produced in terms of layout and facilities improvements, space usability, product/service level and quality, costs reduction and profitability of investments. Concepts like ergonomics, workplace arrangement, flow characterization, paths analysis, human/quality/cost design will be exhaustively treated and prospected. Snapshots of the digital world will be portrayed.

KEYWORDS: Virtual Reality, Digital Factory, Optimization, Manufacturing Environment, Service Industries.

1. INTRODUCTION

In our global marketplace, customers could easily look around in search of better product and services. Factory design, systems analysis and optimization, with shortening of cycle demand, compel designers, engineers and managers to make use of efficient and visionary approaches in the product and process planning phase. A correct and careful planning process, aimed at customer expectation/satisfaction, represents an opportunity to future improvements and benefits. To improve planning results and to carry out customer oriented products/services, and effective production systems, is necessary a reconfigurable and concurrent engineering approach in product, factory design, system configuration [1]. This takes place when all people, who collaborate for the planning, place simultaneously their knowledge at project's disposal [2]. In order to have quality and productiveness, the persons responsible of planning, production and maintenance need to cooperate with the product design group in product’s definition phase. They have to communicate through a common interface [3].

An error into the planning phase manifests much more costs than a “quality management” approach. It is needed most attention to the planning activities that mutually affect the product quality, production process. Anyway, the

\* Fabio Fruggiero: Tel.: (+39) 0971 205196; Fax: (+39) 0971-205160; E-mail: fabio.fruggiero@unibas.it
best way to face up to the gaps is to meet design flimsiness at the early stage of the product lifecycle statement. In the early design stages, the impact of a design change could be minimal because few process plans have been defined and no resources committed. The “Rule of 10” could be applied: the cost of correcting a hundred-dollar mistake in the design phase could increase exponentially across prototyping, setup and production phases to one million dollars after the product has reached the market [4].

The planning phase has generally two main targets: the output, in the form of goods and services, and supply processes. To develop an efficient system, it is necessary to interactively consider the impact of design changes in the plant and process in such a way that the physical manufacturing of the product/service meets quality, time, cost goals and customers satisfaction. Moreover, the traditionally concept of planning phase is as time-consuming (e.g., the product is late on markets), myopic (e.g., mainly looking at product and not process design), out of enterprise context (e.g., poor of customer’s ratings). To overcome these gaps and to maintain the results as planning, the physical model optimization need to be performed. “Virtualizing” the system is a rewarding approach [5]. In the digital environment, alternative process design configurations, in little efforts and time, can be re-engineered and, then, evaluated in a concurrent manufacturing extent of the virtual world (Virtual Manufacturing - VM) [6]. The use of tools and methodologies of digital/virtual prototyping (i.e., Virtual Reality - VR systems) can make easier the system optimization process. Across a computer supported world is possible to visualize and bear out and interplay all elements of the “future” growing factory/environment. This approach gives manufacturing planners early access to in-work designs to allow for concurrent design manufacturing planning and ongoing manufacturing input into design decisions [7]. They can interactively change the layout, resources, machine features, and observe how the system immediately responds [8]. Brainstormings can be founded on visual manifestation of hypothetical arrangements. The bent is leading to deem only after a successful virtual validation the system’s design is implemented and/or modified in the real factory/environment. The 3D visualization of environment is going to be the final output of a more complex optimization procedure [9]. The aim will be a taxonomic rise in workplace ergonomics/pleasantness, workplace/worker safety, increase in productivity, client satisfaction and product/service quality going up overall cost reduction.

In manufacturing, as well as into the Health care management, the digital representation act as a medium to the optimization. In this paper a looped approach between system’s configuration and simulated virtual model has been engaged. The application of digital tools to optimization, from a flow shop manufacturing enterprise to a complex “job shop” service system, are the key elements of the implementations. This paper exhibits the process of developing the optimal layout design and system configuration, and flow analysis by providing the management with multiple layout configurations and showing the impact, basing on simulation output and virtual manifestation, of the arrangement at each stage. It is mainly divided in three section. The first one is dedicated to the Digi ta Factory concept and the definition of optimization process. Firtsly, the authors described the implemented procedure to the optimization and subsequently they spent time into description of the implemented cases. A different section is dedicated for each real implemented settings. The outputs will be described in terms of productivity of capital stocks, reduction of Not Value Added Actions, design flimsiness, quality of services, system lead time, space and usability and accessibility, perception of the labor. Considerations on benefits of such an approach end this work.

2. THE PROCESS POINT OF VIEW IN THE DIGITAL FACTORY APPROACH

To implement a Total Quality Management (TQM) system, a Total Industrial Engineering (TIE) have to be made up by optimizing the supply processes with a consequential rationalization and standardization of human employment and materials handling and flow paths and services [10]. The integration of different tools in digital frame has been implementing into the filed of manufacturing for few years [11]-[12]. This overture has been mainly noted as Digital Factory (i.e., DF). The DF accomplishes the TIE purposes [13].

Digital Factory is the new overture in production systems that “substitutes moving virtual bits for moving physical atoms” [14]. DF is a generic term for a comprehensive network of digital models, methods and tools [15]. It includes product and components characterization and design, data analysis blocks, simulation (e.g., by discrete event models) and optimization procedures, creative problem solving methodologies and virtual ramp up (fig. 1). These are entirely integrated with an upper data management system. DF allows to analyze all aspects that can be observed in a real factory, providing higher insight about the processes, material, fluxes and even human activities and ergonomics [16]. Across the DF approach there is a methodology for organizing the information to the development of the virtual product (i.e., design) and the virtual factory (i.e., planning). The approach links digital design, process and production requirements, and provides a lifecycle view of the complete product definition. The integration of product/process development reduces the system lead-time while improving the process productivity
and quality (of product and process and services) and reducing the overall costs. Its overture facilitates intense collaboration between design and manufacturing planning, from different knowledge background (e.g., engineers and doctors) [17]. Moreover, this approach let them to evaluate designs and make changes, incurring foreseen virtual costs and business risk, quickly and accurately in the virtual development phases when the cost of change is low [18].

Figure 1: The bulks of information in Digital Factory behaviour

A visual optimized approach causes systems designers to think about certain significant issues (e.g., system control and production rise and costumer satisfaction) long before they normally would. The common view of DF framework is as featured by five components fully integrated through a common database for the coordinated management of information generated [19]. Modules for external relationship need to be implemented. This phase is performed by an I/O relationship network pointing out functionalities existing among the element of network. This set the boundaries and the frame of the case in issue. The model structure, the visual ground, the schematization of production system and tasks, the flow and layout analysis are the input data of any modeling phase. In this stage the Product, Process and Resource (i.e., PPR) and Bill Of Material (i.e., BOM) have to be defined. PERT (i.e., Program Evaluation and Review Techniques) and CPM (i.e., Critical Path Methods) are generally used into the modeling phase. Furthermore, the understanding of the probabilistic evolution of the system gives the possibility to implement a consistent model. A statistical data analysis has to be performed in order to depict and bound and prospect the range of alternatives (e.g., a macro identification of trends and possible bottlenecks need to be carried out). The digital simulated implementation accomplishes a complete evaluation of alternatives. A simulated environment is able to dynamically appraising the functioning of the system while evaluating detailed performances for operations choices (i.e., PPR amount). An optimization approach needs to be fixed. It is always defined in order to have a huge database (fulfilling constraints and tabu sets) of possible alternatives. The exploration, while simultaneously exploitation of domain, should be bound up with the definition of a “general purpose” optimization function (mainly based on a balancing assessment) and creative problem solving approach [20]. Modules of final visualization of the system, in 3D digital world, give the possibility to prospect changes and evaluate the results. This approach provides a robust yet flexible configuration management system.

2.1. **THE DIGITAL FACTORY AS A COMPREHENSIVE TOOL FOR TO THE SYSTEM OPTIMIZATION**

As concurrent engineering increases and production cycles shrink, development teams and the systems that support them have to manage a stream of real-time design changes, each requiring routing and reconciliation. In a new view of quality management approach it is possible to substitute the evaluation phase of improvement with a virtual optimization process. The digital 3D world becomes the valuable aspect when clustered units (in knowledge and experience) have to cooperate. Shunting a connection by the Deming (i.e., a cycle of Plan-Do-Check-Act) principles [21], the testing phase of the planning improvements can be evaluated into the virtual model without/before changing the real assets. The procedure of quality improvement can be performed across a cycle of Plan-Virtualize-Check&Optimize-Action. The cycle can be stated as: plan the system, set up a model and individualize problem solution; build the complete model of manufacturing frame (i.e., DF mock-up) in virtual environment; evaluate performances and optimize according to analytic/expert procedures and simulated settings; translate the virtual hub in real world. The advantage is to implement the tasks only after the successful of an
optimization procedure. Moreover, it is just possible to test the solutions which fulfill the requirements of the optimization loop. According with the virtual hub is possible to identify the optimal arrangements and predict results while performing system’s analysis in “fictitious” environment (fig. 2). The understanding change within the context of lifecycle processes and resources as the product matures is the competitive advantage of a digital factory approach.

Starting by a plethora of entry data, the identification of the main features of the model through a statistical assessment phase (shape and modal values need definition) can be accomplished. The representation of the system according with flow charts and mainstream parameters helps to validate the mock-up plans in expert insights. Analyst, managers and engineers have the possibility to validate and modify procedures from different points of view. The optimization of design and plant revamping implies assuming certain compressor conditions to optimize the process. An optimal condition is usually found that optimizes the balance between process turbulence and unjoin unpleasant surprises [22]. A discrete event simulation model, mainly based on meta-heuristic procedures, user defined in relation to the particular problem in issues, helps to analytical evaluate the specified optional configurations [23]. The final optimal arrangement is obtained only after a procedure of visualization in virtual environment where is possible to introduce parameters like space usability, ergonomics, tool handling, maintenances requirements, workstation configurations, tool handling, safety, flow flimsiness and “jam” etc… In this super heated environment, alternatives scenarios could become increasingly diverse and unpredictable. Maintenance may request a change to make it easier to repair; while shop floor staff might ask the manufacturing planner to shift work from one control station to another to improve production flow. Moreover, it is needed to evaluate how human workers and plant resources are impacted by post-production changes. Only visualization structure yield positive results in these cases [24]. The model can be analyzed, and eventually simulated, stating a virtual production mock-up given the available time, space, resources and pointing out alternatives. A decision making process (e.g., Analytic Hierarchy and Network Processes characterization [25]) can be eventually embedded into the event driven simulator. Before comparing alternatives among each other, each scenario is deeply optimized with preliminary runs of the model, that help defining the most appropriate technical configuration, like for example the best worker/staff arrangement, the optimal rota and layout. The 3D model manifests the visual report/output of the implemented optimization process.

2.1.1. The manufacturing environment optimization: A DF investigation into muffler assembly station

A worldwide automotive plant, which produces approximately 250,000 vehicles (in different models and configurations) per year, was analyzed and optimized by the mean of DF approach (table 1). The plant is subdivided in ETUs (Elementary Technology Units); the area under analysis in this paper is the muffler assembly station. The job performed in this ETU, consists of the following operations: exhaust pipe preparation, exhaust pipe assembly, axle assembly, stirrup on hub hand, axle fixing, fixing muffler pipe on the vehicle bodywork, fixing front crossbar, quality control of ETU performances. The ETU is attended by 14 operators, working on three shifts, which produce up to 220 vehicles/day. Statistical data analysis, evaluation of flow paths, safety and quality considerations, cost assessment have been used into the optimization approach [26].

Figure 2: The event flow chart for the process of optimization across the Digital Factory approach
Manual and automated tasks have been simulated into the virtual environment aiming to improve system performance, workspace and worker environment, product quality. In order to investigate new plant configurations and performances, in terms of balanced utilization of resources and saturation rates and service levels to customers, virtual representation/validation have been implemented (fig. 3). Anyway, a database of collected data and an expert analysis identified as the most critical production tasks the catalyst, muffler pipe assembly task and the assembly of muffler pipes on the vehicle. These are going to be the area/jobs/tasks under analysis (fig. 3c). Two or three operators (according to production rate) attend these phases. A worker prepares the catalyst, the pipe (composed by the catalyst, the temperature probe, the metallic gasket and the stirrup) and finally he installs the muffler pipe on the vehicles. The responsible for the muffler pipe assembly on the vehicle brings the completed pipe from the catalyst preparation area and leaves it on a conveyor system; then, the second operator brings the axle from the vessel on the line edge to the conveyor. Subsequently, both operators assemble the break pipes, the ABS sensors and the wire of the hand break (the muffler pipe is mounted on the vehicle in the next station). A conveyor puts the item on the assembly desk. A critical overview to the workplace arrangement and tools handling in simulated virtual environment is able to underline some desirable logistic improvements. These elements can be introduced into the optimization process across to DF mock up. The traditional methods, to ergonomic study, require large amounts of times, due to the subdivision of tasks in basic actions, the evaluation of the key positions (e.g., angles, distances, etc...) and the calculation of the risk indexes [27]. On the other hand, simulated environment and digital dummies, with bio-fidelic kinematics and advanced anthropometric scaling, show how to organize workers’ environment, to design tools, to perform operations and temporize and standardize the tasks [28]. The digital implementation with dummies allows the visual evaluation of not-ergonomic postures, tools, facilities and performs a Motion Time Measurement (i.e., MTM) optimization (fig. 3b). The calculation of NIOSH Lifting Index (i.e., 1.41, 1.46, 1.54 for each operator) [29] and Rapid Upper Limb Assessment (frequency capability near the 60% and mean RULA index 4 as acceptable stress) [30], with percentile and anthropometrical considerations, underlines the validity of tasks in the optimized arrangement. Planning a new configuration of the vessel, workflow and workflow according to the virtual mock-up of the implemented simulated environment carry system to save the 33% of the transport costs (e.g., arranging three rows of vessels on trucks rather than two on initial configuration), with a small investment of €42,150 and a payback period of 8 months (fig. 3a). A Not Value Added Action, performed across the evaluation of different alternatives into the virtual simulated frame gained the reduction of 52%, compared to the original layout, of the distance covered by the operator during workshift. An exhaustive simulation loop prospected the possibility of criticalities for the operator’s safety (i.e., in the procedure of handling the muffler pipe from the assembly bench to the in-line vessel). To avoid all possible contacts of the operator with the muffler pipe, a protection (metallic net) is used; however, it holds over a possible risk for the operators that could get close to the assembly bench. The 3D model of the systems was developed in order to verify in deep details, and manifest in results, optimal paths and construction sequences and assembly solutions to achieve the maximum safety, space and work efficiency. A more focused production structure has been consequently carried out with competitive costs advantages.

2.1.2. FROM MANUFACTURING TO SERVICES: THE DF IMPLEMENTATION INTO AN EMERGENCY DEPARTMENT

The care of patients and quality of services is the main objective of the health care system. Emergency Department (i.e., ED) performance concerns with resource amount and allocations, process standardization, patient’s classification and prioritisation, patient’s waiting and throughput time, queuing disciplines. The objective of this paragraph is to present the application and usefulness of DF approach in a process of optimization of ED services and resources. Across the general approach to the optimization (as described in previous paragraphs) the authors are going to present an extended way-out into digital tools. The lack of standardization into services environment was the main difficulty into the implementation of such a DF model [31].

Figure 4: The Virtual Emergency Department environment in different snapshots.
From the Discrete event simulation view to the 3D virtual environment.

A real Irish Emergency Department has been investigated. Flow paths validation, layout assessment, space usability and procedures’ validation, cost’s estimation and scheduling procedures in alternative configurations/arrangements have been investigated through the implementation DF approach. Modelling the operation (treatments) is very intuitive in DF approach: user can view and prospect each plant workstation and configuration individually in the simulated 3D environment. A user interface has been designed to insert treatment time and to join real and virtual flowing. The optimisation of variables (patient’s throughput time, and number of resources and costs) has been realized and visualized across an optimization routine based on the minimization of a user’s defined function (taking into consideration hospital efficiency and efficacy) [32]. Found on the implementation of a more complex simulation model, pointed on job shop rules, the virtual representation aims to be the validation steps of hypothetical alternatives/configurations and layout in the process of supplying services to patients. The discrete event simulation model tests the system configurations in terms of throughput and waiting time based on defined rules and procedures (the mean patient Waiting Time was evaluated in different configuration, i.e. opt case 214 min, with the characterization of waiting time for first visit, depending on system overcrowding, i.e. Reaction Time as opt 65min, and total Time of Stay into the ED facilities, i.e. opt case 265). While the model is running, the digital manifestation of the environment supports more than a validation opportunity. Moreover, the competitiveness of each scenario strongly depends on conditions not well defined, like from the patient arrival rate, triage level, resource availability. The optimization of the system is mainly based on when the treatment will be available and for how long its supply will be guaranteed. So a correct statistical module and a robust planning model become of fundamental success in such an implementation. The arrival rate (in categories and pathologies) has been “Poissonly” distributed with different shape parameters according to real registration desk data (i.e., the average event in the simulated slot time).

The layout of ED in CUH was investigated in order to improve system’s performance. An analytic optimization procedure based on Quadratic Assignment Process – QAP with heuristic approach [33] represents the implemented mathematical formulation to validate the location of a set of treatments room. The physical facilities of ED in CUH consist of a registration desk (RR), a waiting room (WaitR), a triage room (T), an X-ray area, 12 treatment rooms for major patients (57% of arrival) and 4 beds for minors treatments (32% of arrivals are categorized as minor), 4 resuscitation areas (1.4% of incoming patients need its facilities) and separate stations for the unit secretary, nurses, nurses aides and physicians. The ED treatment zones were switched, in location, considering flow paths and zoning constraints. The flow of patients $f_{ij}$ from facility $i$ to facility $j$, the distance $d_{kl}$ between location $k$ and location $l$, and a weight account (i.e., a function of assignment relevance according to expert analysis) $b_{ik}$ of placing facility $i$ in location $k$ have been analyzed in a combinatorial approach in order to defined a fitness function of allocation. Improvement has been prospected in number of cubicles, mainly for major patients which represents the 57% of arrivals (table 2). The data were modeled as according to the entry registration data. A tabu list forbade the assignment to a particular location (e.g., the location of resuscitation close to ambulance’s entrance). Mathematically the problem is the allocation of a set of facilities to a set of locations [34]. A Simulated Annealing (SA) procedure was implemented [35]. The simulation model permits to evaluate the current process behaviour and to predict the
impact of changes (fig. 4). The scheduling of tasks into the ED facilities were investigated according to a balancing approach with meta-heuristic exploration and exploitation rules. In such an approach the authors considered the impact of different system’s configuration evaluating the number $N$ of resources into the ED system, the workload $W_i$ of resources $k$, the Length of Stay of patient $i$, the Saturation rate between interchangeable, and no, resources. The processing time has been modeled according to Fuzzy rules [36] as after doctors approval. The line balancing approach detects fundamental problems (unnecessary and/or duplicated activities), evaluates the sequence of operation into the department in issue (analysing scheduling process). The authors defined the optimal scheduling in relation to user targets (optimization of patient’s scheduling, patient’s throughput time), and optimal configuration of resources (i.e., in opt case: 8 Nurses, 5 Porters, 3 Registration desk operators, 2 X-Ray technicians, 7 junior doctors - SHO, 6 Register, 1 Specialist called for consulting – see results in table 2).

The advantages of having a 3D-DF approach/model is that while performing a visual discrete event simulation analysis of the flow paths and configurations the managers are able to evaluate the procedures and direct manage the queues. Moreover, the visualization of emergency facilities is able to give users an interplay procedure in the process of fixing main rules and procedures. Inquiries between pathologies (e.g., the testing of the system in case of earthquakes), bed allocation rules (e.g., changing the availability in specific divisions as surgery and/or cardiology), space usage (e.g., testing the waiting areas) and layout opportunities (e.g., evaluating the internal areas for future expansions) have been implemented based on the digital design of the system. The managers impacted directly with proposals and alternative insights. Furthermore the ED facilities were inquired without touching the real services streaming. The quality of the system was assessed in consideration of service level to patients.

3. CONCLUSIONS

The aims of the present paper is to manifest components, application fields and results of the Digital Factory approach to system optimization. The integration of different tools in digital frame has been implementing into the field of manufacturing for few years. Moreover, the DF approach remains enclosed to the industrial environments. Presenting two different cases study, without going into details of results and descriptions (to refer to bibliography for their characterization [24-30-32]), the authors provided how the application of Digital Factory can be exhaustively extended from automotive industrial environment to health care fields. In the present paper the Digital Factory has been characterized in its components. The DF approach has been described in its basic components: modeling, statistical, simulated, optimization and visualized frame. If integrated in a common database of continuous loop they provides a robust yet flexible configuration management system that allows changes to be effective for design only, manufacturing only, or both. In manufacturing as well as in ED services environment, the employment of DF techniques has allowed to optimize layout configuration and its defaults, inefficiencies, product/service quality and costs, space usability, service to patient. Furthermore, in visual environments it is easily the process of balancing the operator’s tasks and rearranging the workshop’s layout. Besides, the imagination of future assessments can be greatly furthered by the creative management of visualization in Virtual Environment.

The authors pointed out and provided for how the application of Digital Factory approach can be exhaustively extended from manufacturing environments to health care fields into a system optimization perspective.

ABSTRACT

The paper presents an approach to a problem of design features decomposition process. Manual decomposition of design features is described. Based on the result of a decomposition process an open structure of design features was worked out. This structure was a base for programming activities. The open structure was implemented with a GRIP language in NX 6.0 system. Thanks to this program modeling of axisymmetric products such as shafts, sleeves and gear wheels is possible. The result of a modeling process is a product model which is recorded as NX 6.0 part and additional by means of the two text files. These files are used for a representation of a product structure, dimensional and tolerance requirements. The open structure of design features was also a base for applying of object programming in order to prepare a CAPP system. In this case an object structure of classes that represents a product model in a CAPP system environment is used.

1. INTRODUCTION

From a definition a technical production preparation consists of a constructional production preparation and a technological process preparation. The constructional process preparation rely on designing of a complete new product or making some modification in an existing product whilst technological production preparation rely on planning of manufacturing processes. A manufacturing process planning is beyond any doubt one of the most important activity in a domain of the technical production preparation. The main goal to reach during this phase of the technical production preparation is to define the whole structure of a manufacturing process, that is a sequence of technological cuts and operations which have to be performed in order to transform a semi-finished product into a product which performs all necessary conditions in relation to: dimensional accuracy, shape accuracy, surface quality. This manufacturing process should also guarantee the minimal manufacturing cost and the minimal labour consumption taking into account available manufacturing resources. There are many methods available for automation of a manufacturing process planning for example: group technology, manufacturing process typification and first of all systems of computer aided process planning – CAPP systems. CAPP systems are usually built with variant, semigenerative or generative method. The variant method is based on the two ideas, the idea of elements/products classification by Mitrofanow/Opitz and the group technology. This kind of a CAPP system is built in the two stages. The first stage is a preparatory stage. During this stage the following tasks are being done: elaboration of a method of elements classification (nowadays the most popular are those which are based on AI techniques application e.g.: neural nets), creation of part/elements families, elaboration of a manufacturing process model for each part family, record of worked out manufacturing processes into a technological database. The second stage is an operating stage during which a new code for a new product is prepared. The product is next classified into a single family. A model of manufacturing process for chosen family is modified in order to adopt it to a product technical description (during the adopting process some of manufacturing operations are modified, some are removed or added). The main disadvantage of the variant method is that it is quite similar to manual manufacturing process planning. It means that during preparatory stage the presence of an expert is needed in order to prepare models of manufacturing processes next stored in the technological database. A generative method and a semi-generative method are alike. The difference between them is slight. In the case of a semi-generative method changing of manufacturing process model is possible. A user can also get unfinished manufacturing process just from a CAPP system and next complete it in manual way. Planning of manufacturing process with a generative CAPP system is based on following assumptions: a product is described by means of a finite set of design features,
for each design feature which has to be manufactured a set of manufacturing variants is worked out. A set of manufacturing variants is a base for making a complete manufacturing process.

1.1. CAD/CAM INTEGRATION

The most critical chain in a data exchange process is an information link between CAD, CAM and CAPP systems. Nowadays these systems act rather in the way of isolated automation islands [2, 3, 5, 8]. It causes that an engineer has not appropriate knowledge about overall manufacturing cost at the design stage. Therefore it can also have a strong influence on a final project economic efficiency. In this case very often appears a question who should be a user of large integrated CAD/CAM/CAE systems such as for example NX 6.0, CATIA etc. in a domain of NC machines programming. Should it be a designer who has certain amount of a technological knowledge? Maybe these actions should be done by a process engineer? This question comes from the fact that in many cases they talk about the integration between CAD, CAM systems but they forget to answer a question what is a source of manufacturing processes plan, what does a manufacturing process plan come from?

The answer to this question is to introduce a CAPP system as an integrator element in a process of data exchange between CAD and CAM systems. The proposed solution in figure 1 is shown. The analysis possibility of potential manufacturing costs at the design stage is an additional advantage of this solution. There is a weak point of this solution, these systems usually work in a batch manner (they usually play a postprocessor role) it means that they begin work as soon as possible but always after finishing the design stage. It unfortunately corresponds to a sequential model of action in a design manufacturing chain. This luck of collaboration between these systems results directly from the lack of the bidirectional communication between CAD/CAPP systems. Therefore is very difficult to implement the concurrent engineering philosophy but there is one solution which can be used in order to solve this problem. This solution will be presented further.

Figure 1: The CAPP system as the integrator element

2. APPLICATION OF OBJECTS TECHNIQUES IN TECHNICAL–ORGANIZATIONAL PRODUCTION PREPARATION

The characteristic feature of an object technique is that its organization is similar to the human world perception. The object technique allows to connect in a particular object compound data structures with procedures which operate on its internal structure. Procedures are also responsible for providing communication between objects. Taking into account requirements which are set during a CAPP system creation process the main advantages of object techniques are as follows [2]:

- objects allow to describe the way of expert thinking and to record his own knowledge,
- objects enable to represent relations, each relation can be also treated as an object,
- classes and class objects allow to describe processes which proceed in real systems.

Term of objects techniques in the case of their application in the process of computer aided technical-organizational production preparation is considered dually. It means that author on the one hand by term of object techniques mean: design, technological and functional features and one the other hand mean OOT techniques such as: object oriented analysis, design and programming. In the first case features techniques is used for a product design representation, manufacturing technology representation. A product is represented by means of a set of design features. Each particular design feature represents particular distinguished feature of a product. In the case of
application of design features for a design representation, selection of the method of building of constructional database is needed. The constructional database contains information about prototypes of particular objects. Nowadays the most common used methods for constructional database building are [4, 5, 6, 8, 12]:

- methods of feature recognition,
- methods of automatic features decomposition,
- the manual method of an arbitrary decomposition of features.

In the presented work the third method of constructional database building was employed for the sake of its advantages such as: possibility of participation of experts in a process of features decomposition (this guarantees proper degree of database representative), the greater speed of the decomposition process in comparison with other methods, implementation and database developing ease. This method is appropriate for a database building for each kind of products but the scope of the present work is limited to the group of axisymmetric products such as shafts, sleeves and gear wheels. This limitation was made because for this group of products a feature identification process is simpler in comparison with other groups of products. It comes from the fact that for a group of frames for example only a part of surfaces is treated while the rest of surfaces remain in their previous state which comes from the previous manufacturing processes (i.e. cast). In the case of axisymmetric parts in principle, apart of semi-finished product all product surfaces are treated. In figure 2 we can see a model of a shaft and design features which were manually decomposed from the shaft model by an expert.

An expert during the decomposition process distinguished in the shaft model the following design features: pins marked out with symbols CZW1÷4, chamfers FZZ1÷2, fillets PPR1÷2, center holes NAK1÷2 and one design feature WW1 which denotes splines (note, all abbreviations come from Polish if you want to write them in English you can call them for example CLP1 which means cylindrical pin no. 1, CHO1 – center hole 1 etc.).
A design modeling process with the design features method use can be realized in the following three ways:

- the incremental method – the constructional method, in this case a product model is created step by step by adding following features to each other. It corresponds to a rapid manufacturing process.

- the removal method – the technological method, a product model is created by removing following constructional features from a semi-finished product. For axisymmetric products it corresponds to removal process that is realized in the real world on a turning machine;

- the mixed method – the constructional-technological method, a product model is created by adding or subtraction particular objects to each other.

From author point of view the best method for designing a CAPP module (if a CAPP module is a part of a CAD system) is the technological method for the sake of its similarity to a manufacturing process. If the technological method is implemented, CAD system plays a role of a data source about a product model in the special way. Therefore it is possible to make a user interface in such a way that allows to make a technological process in the background. Using this scenario a CAD system user makes a product model and a model structure. This model structure is nothing other the structure of a manufacturing process of a product it means the order of design features corresponds to a sequence of manufacturing operation and cuts. In this case a CAPP system inference engine has a very simple structure. In spite of undoubted advantages of this solution it is efficiency is in principle limited to a group of axisymmetric parts such as shafts, sleeves etc. If one wants to widen a filed of system action to other group of products (frames, levers etc.) it is necessary to work out an application which works in a CAD system environment with the constructional–technological method. Moreover the paper author considers that application of the constructional-technological method from a user point of view is more friendly. For example a modeling process of shaft in this case rely on inserting following design features such as shaft pins in order to get a rough shape of a shaft. This shape of a shaft corresponds to a state of a manufacturing process after rough manufacturing. The difference between the rough shape of the shaft and the shape we get after rough manufacturing is as follows: during the modeling process we model a product without taking into consideration dimensional deviations – we model it just for nominal dimensions whilst after rough machining some dimensional deviations can stay over some shafts pins. Next the final shape of a shaft is made by subtracting design features such as: grooves, undercuts etc. The modeling process with constructional–technological method in figure 3 is shown.

![Diagram](image-url)

Figure 3: The modeling process with mixed (constructional–technological) method
Figure 4 presents the open structure of design features worked out at the present stage of the research. The identification process of design features was led taking into account the following rule, for each particular design feature a single machining cut, an alternative machining cut, group of machining cuts or alternative group of machining cuts should be ascribed. It corresponds to the situation in which a single manufacturing feature or group of manufacturing features (machining operations or cuts) corresponds to a particular design feature. This type of connections answers to relations such as one-to-one or one-to-multi. Such a definition of relations which appear between design and manufacturing features makes process of a CAPP system design and implementation much simpler.

Figure 4: The open structure of design features
Appearance of relations one-to-multi is very important from collaboration between CAPP and CAP/PPC point of view. Accessibility of this kind of relation allows to create multivariant technological routes. It is essential in the case of systems which are able to solve problems connected with scheduling and rescheduling problem taking into consideration possibility of disturbance appearance.

In figure 4 we can distinguish the two kind of lines: the dash–dot line that sets a border of classes which are used in the incremental way (constructional method) and the dot line that sets a border of classes which are used in the removal way (technological method). In the mixed method both type of classes are used. The mixed method makes possible to widen a CAPP system action filed to a group of products which do not belong to the group of axisymmetric parts. The open structure (see figure 4) was base for programming activities. This structure was implemented into two different environments. In CAD system it was implemented with GRIP language whilst in the CAPP system it was implemented in Borland Developer Studio 2006.

The GRIP language is a procedural programming language therefore it does not support the object paradigm. In order to simulate object behavior for a set of design features, structure of each design feature was written in a separate program module. It means that the number of modules has to be equal to the number of design features excluding modules responsible for a database management and other activities which are not connected with design representation. Each program module corresponds to a structure of a class in the object paradigm. Of course it is not possible to make hierarchy of modules in this way as it is made in the case of classes; as we know this opportunity is the most powerful advantage of object programming languages. So, why is it worth writing this structure in separate modules instead of writing it into a one large program, the answer is very simple. When program is divided into many separate modules we can make same changes in our program by changing code of a single module so it is quite impossible to damage the rest of program code. Moreover if we make some mistakes in the code of a module the rest of the program can work without any problem. If the open structure is written in the one large program when we make same changes in its code there is a high risk of damaging our program. Recording of a design feature in the way of separate modules allows to develop program simply and quickly by adding a call to a new developed module into a management module. Worked out program is next used in the Unigraphics/NX 6.0 environment in a batch manner. This program called SHAFT–CAD consists of a management module, modules that represent particular design features as it was written above and modules responsible for a selection data from a standards database. The structure of SHAFT–CAD program in figure 5 is shown.

![Diagram of SHAFT-CAD program](image)

In figure 5 the following abbreviations were introduced: MM – a management module, DFD – a design feature database (organized as a set of separate modules), SDMM’s – management modules group responsible for a standard database servicing, SD – a standard database, NX 6.0 – environment of CAD/CAM/CAE system. A user of the SHAFT–CAD program begins its work with modeling a rough shape of a model by adding following shaft’s pins one to another. If the rough shape of the model is finished a user can add to the model features which are subtracted from the rough model so one gets a finished product model. A user of this software is supported by SDMM’s modules during a modeling process. For example, in the case of inserting a design feature that has a standard shape and dimensions (grooves, undercuts, threads, etc.) standard data are introduced into appropriate edit boxes of a user interface window automatically according to a suitable standard. We have to remember that in same cases the design feature dimensions are strictly connected with pin’s dimensions. If SDMM module cannot match feature dimensions with pin’s dimensions in accordance with a selection rule for example, an automatic selection is
impossible. In this case, as it is said in the fuzzy logic it is better to give a user an answer that is sure for 80%, for example, instead not giving him any answer. Therefore program tries to propose same data values and a user has to check and correct them. The SHAFT–CAD program plays a preprocessor role for a CAPP system so SHAFT–CAD is responsible for product data recording. A product data consists of an information about product structure – relations between particular design features used in modeling process, a shape and dimensions of design features. The information about a product structure in a text file with *.stc extension is recorded whilst a model geometry it is particular design feature dimensions in a text file with *.geo extension is recorded. This information is next used by a CAPP system in order to prepare a manufacturing process. The modeling process with SHAFT–CAD use in figure 6 is shown. A form of a model structure file and geometry file in figure 7 is shown.

Figure 6: The modeling process in the SHAFT–CAD program, a) the rough shape of a shaft, b) the finished shape of a shaft

SUMMARY

At the present stage of a software development a SHAFT–CAD program works in the NX 6.0 environment and a CAPP system works beyond this environment. It seems to be the biggest disadvantage of this solution. Moreover implementation of the GRIP language in order to record a design features database is not the best solution because in this case is not possible to implement object paradigm fully. Additionally this solution does not support the bidirectional information exchange between CAD and CAPP systems. In order to solve this problem author of this work considers:

- based on worked out open structure of design features create a new one CAD module working in NX 6.0 environment but now implemented with OPEN/API C++ language. In order to make this module, elaboration of an object classes structure is needed, a classes structure working in a CAPP system can be used after making same modifications;

- a CAPP system should work in the NX 6.0 environment, should be written with OPEN/API C++ language.

If above assumptions will be satisfied the bidirectional information exchange between CAD/CAPP systems will be performed. It means that at the design stage a designer will have full information about design cost and he will be able to make same changes in a design during a manufacturing process planning stage. A CAPP system with its object design representation will give some information for a CAM module so full integration between CAPP system and CAM module will be performed.

ACKNOWLEDGEMENT

The presented research work was financially supported by Polish Ministry of Science and Higher Education in the framework of the N115 081 31/1906 project entitled: Integrated system of adding of a technical-organizational production preparation for small and medium enterprises.

ABSTRACT

Over the last 50 years there have been many significant enhancements in computer aided systems which have influenced CNC technology. One area that can be considered as a bottleneck to these CNC enhancements and in particular to interoperability in CNC manufacturing is G&M part programming (ISO6983). To overcome this bottleneck, the new standard ISO 14649, known as STEP-NC, is being developed to provide detailed information on component design, process planning and machining strategies to manufacture parts for the next generation of intelligent CNCs. This standard forms the basis of a new paradigm shift in the CNC domain to support the digital modeling of CNC manufacturing resources. The research in this paper aims to identify major issues and develop new software tools to demonstrate the feasibility of interoperable CNC manufacturing based on STEP-NC. This paper proposes a Process Planning System (PPS) with surface roughness chosen as the process planning objective. There are five modules in the system: program reader, process planner, STEP-NC CAD viewer, STEP-NC CAM viewer and program writer. The reader is responsible to interpret the geometry and the manufacturing data from a STEP-NC file into a stored data list. The process planner uses this data list and enables users to evaluate surface roughness based on a mathematical model. Through the STEP-NC CAD viewer, the part geometry can be shown and via the STEP-NC CAM viewer the toolpath can be verified. Finally, the writer converts the stored STEP-NC data of the system into an updated STEP-NC file. An example case study component is used to demonstrate the PPS and show the interfacing of the STEP-NC data.

1. INTRODUCTION

From its emergence in 1952, the numerical control machine tool has undergone significant improvements and has provided an ever-increasing important part in manufacturing. Many other relating technologies, including CAD, CAM, CAPP, have advanced greatly coupling with the enhancement of the computer technology. However, the early NC machines and today’s modern CNCs utilize the same standard for programming, namely G&M codes formalized as ISO 6983. It is a common consensus that the unchanged standard has become a bottleneck of the advancement of CNC manufacturing because of the data noncompliance through the CAD/CAPP/CAM/CNC chain [1]. To eliminate the problem, a new standard extending STEP into manufacturing has been developed, which is formalized as ISO 14649 commonly known as STEP-NC. Unlike the G&M codes, which program the movements of the machine axes and switches, STEP-NC is a comprehensive data model that associates the machining objectives (CAD design data) with solutions (CAM process data required) in an object-oriented way. Furthermore, it builds up a bi-directional information highway between the CAD/CAM and CNC systems [2] and makes interoperable process planning and manufacturing possible [3]. Although it is believed that the new standard will undoubtedly introduce interoperability into manufacturing, due to the inherent complexity of STEP compliant CNC controllers, a global interoperable STEP-NC system is still a long way away [4].

Recently, there have been a number of major developments achieved in the STEP-NC based interoperable research. In the research area of STEP-NC compliant controller, a TurnSTEP has been developed by Suh et al. [5], which can convert STEP-NC part program into tool motion to get the designed part. Xu et al. [6] developed a STEPcNC converter used on an existing CNC machine tool to enable it to be G-codes free. Heusinger et al. [7] present a methodology for implementation of a CAx chain for rotational asymmetric parts. The necessary data models were created and tested through a prototype system. A framework for a multi-agent-based STEP-NC...
controller was proposed by Lan et al. [8] with a prototype system has been developed with the tool of ST-developer for the framework. In the research area of STEP compliant process planning, a three-stage process planning model was proposed by Liu et al. [9] using a feature-based approach, which divides process-related issues into three levels: offline process planning, shop-floor process planning and real-time process planning.

STEP-NC provides a real opportunity and challenge to promote the improved manufacturing capability utilizing high level and detailed information. To date, most STEP-NC systems focus on milling operation. In this research, a Process Planning System (PPS) for the next generation controller for turning is proposed. This paper introduces the PPS and outlines the mathematical model on which process planning is carried out. Finally, an example component is used to demonstrate the application of the system.

2. STEP-NC PROCESS PLANNING SYSTEM(PPS) ARCHITECTURE

For the next-generation interoperable CNC controller, a multi-agent-based intelligent STEP-NC controller has been proposed by Lan et al [8], which is comprised of many agents. These agents undertake specific tasks and accomplish them by interacting with others to carry out the various functions of an intelligent controller in a desired manner. The STEP-NC Process Planning System (PPS) which has been adapted from this approach consists of three agents based on this architecture namely: the program interpreter agent (STEP-NC data reader), process planner agent and program generator agent (STEP-NC data writer). The emphasis of this research is the implementation of the process planning agent.

PPS consists of five modules namely: program reader, process planner, STEP-NC CAD viewer, STEP-NC CAM viewer and program writer as shown in Figure 1. In the process planner module, project optimization is made by adjusting specific parameters and the workingsteps’ sequences, etc. Process planning has numerous criteria that can form the objective of the plan (e.g. minimum processing time, cost etc.). To limit the scope of this research, the surface roughness has been chosen as optimization objective. With the mathematical model outlined in section 3.2, the user compares different machining strategies with different parameters (e.g. feeds, tools insert types etc.). The intended toolpath of the machine is generated by the toolpath generator. The toolpath planned can be shown and evaluated in the STEP-NC CAM viewer, as described in section 4.

The basis of PPS is the STEP-NC data and consequently, the system contains other function modules including program reader, program writer and the STEP-NC CAD and CAM viewers. With the input of the system being a STEP-NC Part21 file, the data reader checks it and translates it into an internal data format (Java ArrayList). The data is organized by the relationship inherited by the STEP-NC file, utilizing the advantage of the object-oriented programming language Java, such as strong types, inheritance and polymorphism [10]. The process planner provides a graphical interface to display and modify the particular information associated with each feature and operation. After changing the manufacturing parameters, it is essential to check whether these changes contribute to enhance the final part based on the roughness mathematical model. Then, the updated data list could be transferred to the Data Writer to generate a new STEP-NC compliant program with the manufacturing information stored in ISO 14649 format. The ultimate output is a STEP part21 physical file (.stp file). During the process, there are several visualization tools that have been realized to view the STEP-NC data, the final part, the manufacturing features and the toolpath generated by the toolpath generator.

3. PROCESS PLANNER

3.1 STEP-NC PROCESS PLANNER

According to Liu et al. [9], process planning is divided into three levels: off-line, shopfloor and real-time. At the off-line process planning level, a NC program is generated with the CAD design information and other technology requirements of the final part. The activities involved in shop-floor process planning consist of:

i) Manufacturability Analysis: assessing the whole machining ability with all the resources available.

ii) Workingstep-level Planning: optimizing the parameters for every single workingstep.

iii) Part-level Planning: determining the best workingstep sequence for a particular project.

iv) Manufacturing Resource Planning: choosing suitable tools, clamps etc.
At the level of real-time process planning, the toolpath and additional machine function switches (e.g. turn coolant on/off etc.) are produced according to the current machine status. PPS is applicable to both the shopfloor and the real-time process planning levels. The process planner module can be applied at the shopfloor process planning level while the toolpath generator would typically be used at the real-time level.

Manufacturability Analysis is achieved by the operators according to their experience, while the other three activities are achieved by PPS through system interfaces to modify the stored STEP-NC data. These interfaces are shown in Figure 2 and 3. The first interface (Figure 2) is used to adjust the workingstep sequence and the interface in Figure 3 is for workingstep parameters changing, which can generate a surface roughness report.

In Figure 2, the interface shows for SETUP 1, with its workingsteps listed in the WS-IN and the workingsteps in the WS-REST area related to other setup(s). Using this interface, the user can add workingsteps into the chosen setup and delete workingsteps from the chosen setup. The user also can adjust the sequence of the workingsteps within a setup. If another setup is chosen, the WS-IN and WS-REST data will change correspondingly.

In Figure 3, the parameters of a workingstep are visualized in different groups. It is feasible to change some of them according to the user’s experience. Before saving the changes, the user can gain help by pressing the button of roughness report from the surface roughness prediction mathematical model to determine whether the changes contribute to enhance the quality of the part. The pop-up shows the surface roughness report based on the data of the workingstep. The surface roughness prediction mathematical model is outlined in next section.
3.2 SURFACE ROUGHNESS MODEL

There are many different options for the workingstep parameter optimization based on a wide range of goals. As described previously, surface roughness has been chosen to be the optimization objective in this research. As is commonly known, the surface roughness is mainly caused by the height of the residual area, which makes the surface when magnified look like a threaded uneven pattern. The roughness value of a part can only be obtained by measurement after it is completed, which is merely the criterion to determine whether it is qualified or not. From using the detailed workingstep and operation data in STEP-NC, it is possible to provide a standardized approach to predict and verify the surface quality of the product. As there are many elements that influence the surface quality of a part, with many of them being dependent on a particular manufacturing resource, the process planner can at most reach a level to compare different ways of machining using the mathematical model of the residual area’s height as depicted in Figure 4.

In turning operations, the tool and the workpiece have a relative helical motion which inevitably results in the residual area on the surface. The surface roughness is mainly caused by the height of the residual area together with the influence of other factors. Theoretically, the residual area height is the surface roughness. The height of the residual area depends on the major tool cutting edge angle (in STEP-NC, it is called side cutting edge angle) $K_r$, minor tool cutting edge angle (in STEP-NC, end cutting edge angle) $K'_r$, tool nose radius $r$ and the feed rate $f$. According to the relationship of the values of tool nose radius and feed rate, the residual area height is shown in three different cases as shown in Figure 4 [11]:
For a large tool nose radius with a low feed rate \((f < 2r \cdot \sin K_r')\), as shown in Figure 4 (a), the residual area height depends on the \(r\) and the \(f\), where \(r\) is the tool nose radius and \(f\) is the feed rate:

\[
h = \frac{f^2}{8r} \tag{1}
\]

For a high feed rate with a small tool nose radius \((f \geq 2r \cdot \sin K_r')\), as shown in Figure 4(b), the residual area is thought to be caused by the tool nose \(r\) and the minor cutting edge \(K_r'\). The height is calculated as follows:

\[
h = r(1 - \cos K_r' + F \cdot \cos K_r' - \sin K_r'\sqrt{2F - F^2})
\]

where \(F = f \cdot \sin K_r' / r\).

When \(r=0\), as shown in Figure 4(c), the residual area height depends on the feed rate \(f\) the major tool cutting edge angle \(K_r\) and the minor tool cutting edge angle \(K_r'\), where \(r\) is the tool nose radius and \(f\) is the feed rate:

\[
h = \frac{f}{c \tan K_r + c \tan K_r'} \tag{3}
\]

(a) for a large tool nose radius  
(b) for a high feed rate  
(c) \(r=0\)

Figure 4 The residual area height \((h)\)

In the case of the example shown in Figure 3, Equation 1 is used above with the values of \(r=1.0\, \text{mm}, K_r'=10^\circ\) and \(f=0.3\, \text{mm/rev}\). This as shown from the roughness report dialogue gives a value for \(h\) of 0.01125mm.

4. TOOLPATH GENERATOR

The STEP-NC CAD and CAM viewers provide the user with a virtual and graphical interface of the part geometry and the machining toolpath. The major capability developed in these viewers is the toolpath generation to get the tool cutters center lines.

4.1 THE SELECTION OF THE TOOLPATH PLANNING UNIT

There are three feasible options for the toolpath planning unit based on STEP-NC, which are the manufacturing-feature, machining-operation and workingstep. According to the STEP-NC standard, manufacturing features contain three different kinds of information: geometry shape dimension, quality requirement, workpiece information including material category, dimensions etc. These three forms of information do not provide enough data to generate the machining toolpath. The other decisive factors of the toolpath are the turning technology and strategy, which are stored in machining-operations. Both the manufacturing-feature and machining-operation needs to be combined with each other to generate the final path. Consequently, the workingstep, containing the manufacturing-feature and the machining-operation, has been chosen to be the path planning unit. It can be described as using an operation to machine a feature. Additionally, the workingstep is an executable unit in STEP-NC, which means, the consequence of workingsteps is the correct procedure to undertake the machining of the product.
4.2 The procedure of toolpath planning

4.2.1 Material Removal

Firstly, it is essential to determine which piece of material to remove from the stock. In the example program of ISO14649-12 as shown in the Figure 5 for the case study part shown in Figure 6, line #40 represents a workingstep in the program, with a feature (#12) and an operation (#20) defined. According to the feature of #12, its workpiece is defined in #1, and its feature outline is defined in #200.

From the program line #4 in Figure 5, it is obvious that the rough workpiece is circular with a length of 175mm and a radius of 37.5mm. The feature outline is defined by five points in its own coordinate system, which is shown in the Figure 7 [12]. It is thus easy to determine what material needs to be removed from this workingstep.

4.2.2 Machine Strategies

In STEP-NC, to identify the material removal strategy, the attribute of the operation named machining strategy is used. Examples of machining strategies defined for turning are namely (a) unidirectional turning, (b) bidirectional turning, and (c) contouring turning as shown in Figure 8. As previously discussed, the machining strategy is crucial to the toolpath planning, which is specified by the operation. Within the workingstep in the manufacturing workingstep segment (#40), the operation (#20) to rough the feature (#12) in the program is also shown in figure 5.

In this machining operation segment (#20), the first $ identifies that the toolpath of the operation is not specified yet. This is due to the fact that it is expected to be generated at the intelligent STEP-NC CNC. The retract plane is represented by the number 30.000 in millimeter, and the machining allowance of this operation is identified by the number 0.5 in millimeter.
The machining strategy is defined in line #131. From this line, the following information is specified:

i) Unidirectional turning.

ii) Multiple turning. This is omitted but could be determined by the controller intelligently with the final incremental cutting depth being 3.000mm and the height of the tool retraction height being 2.000mm. While the maximum depth to be removed is apparently much bigger than 3.000mm, consequently, the property value is true.

iii) Cutting depth list. Each entry of the cutting depth list stands for the thickness (not the total depth) that shall be removed in the respective pass until all the material to be removed is removed. If there are more passes needed than list entries, the last entry shall be used for the remaining passes [12]. In this program, the 3.000 is the cutting depth of the last pass, and the depth for other passes should be implemented by the controller. As shown in Figure 7 above, the maximum depth is 15.96mm. The whole cutting depth could be assigned as (0.96, 3, 3, 3, 3, 3) in mm.

iv) Feed direction. The direction could be specified to be parallel to the Z-axis pointing to smaller values of Z.

v) Lift direction and stepover direction. Because they are both not given in the program, in this paper, the ordinary manner is the choice: vertical lift and horizontal retreat.

With the parameters above, the final toolpath could be calculated as shown Figure 9. In the similar way, the toolpath of the rough operations in the first setup could be illustrated in the STEP-NC CAM viewer as shown in Figure 10.
6. CONCLUSIONS

This paper has proposed and demonstrated a process planning system based on STEP-NC, which can serve as the interpreter and process planner for the whole architecture of the STEP compliant NC controller. The major conclusions of this work are:

i) The STEP-NC data can be used for generic a standardized data for genetic process planning and toolpath generation for turning operations.

ii) The incorporation of the surface roughness module the STEP-NC PPS can be integrated with STEP-NC data to generate process plans which manufactures part with a prediction of surface roughness.

This research illustrates the potential that a STEP-NC data model provides the basis for future detailed standardized process planning and verified machining.

ACKNOWLEDGEMENTS

The work reported in this paper has been supported by a number of grants for Engineering and Physical Sciences Research Council (EPSRC), involving a large number of industrial collaborators. In particular, current research is being undertaken as part of the EPSRC Innovative design and Manufacturing Research Centre at the University of Bath (reference GR/R67507/01). Mathematical model of 6-axis CNC spiral bevel and hypoid milling machine

Piotr Skawinski¹
Warsaw University of Technology
The Faculty of Automotive and Construction Machinery Engineering, Warsaw, Poland

**ABSTRACT**

*Spiral Bevel Technology Group (SBTG) is utilized in the design and manufacturing of spiral and hypoid bevel gears. The CAD/CAM system developed by SBTG for design and manufacturing of spiral and hypoid bevel gears generally supports conventional machines. This modern technology of spiral bevel gears engages the CNC milling machine or grinding machine. Therefore, it is necessary to add to the computer system a machine setup for CNC milling machines. The six independent orthogonal mechanical freedoms (X, Y, Z, A, B and C) set the relations between the cutter head and work-piece. The mathematical model of CNC milling machine accepts basic technological conventional machine settings and transforms these settings to the six axes. The model of the CNC milling machine is determined by specific vectors.*

1. **INTRODUCTION**

The base for each cutting of spiral bevel gears is generated in the machine space technological setup which contains generating gear and a blank work-piece. The generating gear is represented by cutter head and cradle. The generating gear and work-piece are rolled accordingly to the ratio of roll and the tooth profile cutting. Generally, on the conventional machine there are two types of generating gears: with flat crown gear and cone crown gear (Figure 1). CNC milling machines should allow manufacture gears in all technological methods which are accessible in conventional machines. It means that these machines should allow the ability to generate in their space the same types of generating gears.

![Figure1: Generating gear [3] for conventional machine: a) flat crown gear, b) cone crown gear](image)

Mathematical model of 6-axis CNC spiral bevel and hypoid milling machine

2. CONVENTIONAL MACHINE

A conventional machine for spiral and hypoid bevel gears has two units: cradle unit and work unit mounted on the machine frame. The cradle unit is equipped with a tool spindle, and depending on machine construction, the cutter axis is fixed parallel to cradle axis. The cradle unit includes the modified roll mechanism (Figure 1a) or the special mechanism that allows tilting (Figure 1b). The schematic of conventional machine with tilted cutter axis is shown in figure 2. The machines with the cutter tilt unit are very often equipped with a modified roll mechanism. It means, that such a machine allows usage of all technological methods for generating gears and formatting gears.

![Figure 2: Conventional machine [4]: 1- cradle units, 2 – cradle, 3 – eccentricity, 4 - swivel angle, 5 - cutter spindle rotation angle, 6 – work-piece unit, 7 – blank offset, 8 – frame](image)

The settings of conventional machine are following:
- cradle angle – angular position of cutter at calculation point,
- eccentricity - radial position cutter axis (set as angle of eccentricity),
- swivel angle - angle of cutter axis orientation,
- cutter spindle rotation angle (tilt) – angle between cradle axis and cutter axis,
- work offset (hypoid) – distance in vertical plane between cradle and work axis,
- root angle – the angle in horizontal plane between cradle and work axis,
- head setting – linear adjustment along work axis,
- sliding base – linear adjustment along cradle axis – the depth of cut,
- ratio of roll – decimal ratio between cradle and work (tooth profile generation),
- index ratio – only for continuously cutting (face-hobbing method) – controls the relation between number of group of cutter blades and number of teeth,
- helical motion – for technological method with helical motion during rolling motion.

The first eight settings determine relative position of the cradle and work-piece in the machine space and these settings do not change during the cutting process. The remaining settings determine the kinematics of generating
process. It is necessary during a generation process to change the following settings: cradle angle as a result of rolling motion and accordingly to this ratio of roll, pinion rotation. If it is done under continuous cutting (face hobbing), than the index ratio controls this relation between number of group of cutter blades and number of teeth in opposite to single indexing cutting. The index ratio independently of face hobbing or face milling has no influence on the generating motion (tooth profile).

3. BASIC TECHNOLOGICAL SETTINGS

Basic technological settings will be described for machines with cutter axis tilt as a general solution. In this case, a cone crown gear is generated in the machine space. For cutter tilt equaled to zero, a flat crown gear is generated in the machine space and, therefore, a swivel angle has no influence on generating gears. Figure 3 shows schematically this basic technological setup.

Figure 3: Izometric view of basic technological setup.

Figure 4: XZ plane of basic technological setup
Based on the analysis of the basic technological setup (Figures 3, 4, 5) it is necessary to define at the start some important points. Point $O_M$ is the machine center. Point $O_G$ is on the cutter axis at the plane tangent to the top of blades. Point $O_P$ is located on the pinion (gear) axis and is the top point of the pitch cone. These three points allow definition of the following settings:

- cradle angle $q$ in the XY plane (cradle plane) defined by radial setting $U$ and $X$ axis,
- radial setting $U$ as a distance in the cradle plane (XY plane) from machine center $O_M$ to cutter center $O_G$,
- swivel angle $j$ which defines the direction of cutter axis tilt. This angle is determined as a projection angle on the cradle plane and lies between perpendicular plane to the radial setting $O_MO_G$ and the plane $\lambda$ in which the cutter axis is tilted.
- cutter spindle rotation angle, tilt angle $I$ formed by cutter axis which lies on the $\lambda$ plane and cradle axis.
- root angle $\delta_M$ in the horizontal (XZ) plane formed by work axis and cradle plane XY.
- work offset $a_M$ as the distance between the cradle axis and work-piece axis. This distance is measured up or down to machine center $O_M$.
- head setting $X_P$ is the distance in the XZ plane measured along work axis between $O_P$ point and $O_{PM}$. Point $O_{PM}$ is the crossing point of work axis and parallel line to the $Z$ axis in $a_M$ distance and perpendicular to Y axis.
- sliding base $X_b$ as a distance between machine center $O_M$ and point $O_{PM}$ in perpendicular direction to the cradle plane.

These values determine the virtual machine settings as linear and angular parameters and describe the relative geometric positioning between cutter head and work-piece. The virtual machine settings should be completed in the kinematic relations between cutter and work-piece for the hobbing and milling methods, first: as the rotational position which complies the ratio of roll motion, second: as the rotational relation between number of blade groups of cutter and number of teeth for continuous indexing (hobbing method - Oerlikon/Klingelnberg technology). For the Formate methods (Gleason technology) and for the gear cutting when the cradle motion is fixed, the virtual machine settings are described only by eight geometric parameters.
4. Mathematical model of 6-axis CNC machine

Generally, the work space of CNC cutting machines is determined by the Cartesian coordinates. The number of coordinates depends on number of axes which are necessary to note the relation between tool and work-piece. For example, for a simple turning operation two axes are necessary; however, for the milling operation two, three or more (maximum five) axes are necessary. For the CNC bevel gear machine six independent coordinates describe the relative position between the cutter head and work-piece. The schematic drawing of the 6-axis CNC bevel gear machine is shown on Figure 6.

CNC machine uses 6 axis: three linear and three rotational axis which are as following:
- X - horizontal movement perpendicular to cutter head axis,
- Y – vertical movement perpendicular to cutter head axis,
- Z – horizontal movement parallel to cutter head axis,
- A – rotation of work-piece about its axis
- B – rotation of the work head about vertical axis parallel to the Y axis,
- C – rotation of the cutter head about its axis.

The mathematical model of the 6-axis CNC bevel machine is the registration of relative positioning of the tool and work-piece in which continuous changes occur between the axes. According to Figure 7 and 8, point O_M is the beginning (zero point) of the machine coordinates. These machine coordinates are the global coordinates in the machine work space. In opposite to a conventional machine, the CNC machine does not have a work-piece offset as the mechanical displacement of work-piece unit (see Figure 2). It means that the work-piece unit is more rigid than the same unit in the conventional machine. In the CNC solution, the work-piece offset is realized by the movement of the local coordinates. Typical cradle for the conventional machine is replaced with the special unit, in which elements move in perpendicular direction as X and Y axes (Figure 6). The XY plane is the cradle plane and the continuous changes on each axis effect the cradle rotation. The Z axis is perpendicular to the XY plane and parallel to the cutter axis and it controls the movements of the work-piece unit (table unit) towards the XY plane (the cradle plane). The CNC machine does not have a cutter tilt unit, but it is possible to realize the technological methods with cutter tilt as SFT (Spiral Formate Tilt), HFT (Hypoid Formate Tilt), and other similar approaches. Because of the continuous transformation of coordinates (Figure 7) by a controller during generating motion it is possible to hold the cutter axis and work axis at the same relative orientation, like in the conventional machine. The B axis of the CNC machine is the rotation about Y and it corresponds to root angle from the basic technological setup. Axes A and C require an additional explanation. For single indexing (Gleason technology), the rotational position of work-piece depends on generating motion connected with the XY cradle position and does not depend on the rotational cutter position. Continuous indexing requires, independently of generating motion (Oerlikon/Klingelnberg
Mathematical model of 6-axis CNC spiral bevel and hypoid milling machine

technology), a very close relation between angular position of the number of blade groups of cutter and number of cutting teeth. In both cases, the C axis is controlled by cutting speed. A mathematical model of CNC machine is supported on the basic technological settings for the conventional machine which have been listed above (10 settings), but determined in the 6 - axis (6 mechanical freedoms) of the Cartesian coordinates.

Figure 8: Coordinates system for 6-axis CNC machine

Vector $\mathbf{PO}$ along work-piece axis is defined:

$$\mathbf{PO} = [-\cos \delta_M, 0, -\sin \delta_M]$$  \hspace{1cm} 3.1

Vector $\mathbf{t}$ along tool axis:

$$\mathbf{t} = \left[ -\sin(i) \sin(q-j), \sin(i) \cos(q-j), \cos(i) \right]$$  \hspace{1cm} 3.2

The unit vector $\mathbf{p}$ and $\mathbf{t}$ of work-piece and cutter position:
Mathematical model of 6-axis CNC spiral bevel and hypoid milling machine

\[ \mathbf{p} = [-\sin\delta_M, 0, \cos\delta_M] \]
\[ \mathbf{r} = [-\sin(q-j), \cos(q-j), 0] \]

Vector from point \(O_G\) to point \(O_{PM}\):

\[ \mathbf{Q} = [-U \cos q, (U \sin q - a_M), x_B] - A_{MDt} \mathbf{P}\mathbf{O} + H \mathbf{r} \]

where:
- \(U\) – radial setting
- \(q\) – cradle angle
- \(i\) – tilt angle
- \(j\) – swivel angle
- \(\delta_M\) – root angle
- \(a_M\) – hypopid offset
- \(x_B\) – sliding base
- \(A_{MDt}\) – mounting distance
- \(H\) – height of cutter

Unit vectors of orthogonal axes are determined:

\[ \mathbf{\hat{W}_Y} = \frac{\mathbf{P}\mathbf{O} \times \mathbf{r}}{|\mathbf{P}\mathbf{O} \times \mathbf{r}|} \]
\[ \mathbf{\hat{W}_Z} = \mathbf{r} \]
\[ \mathbf{\hat{W}_X} = \mathbf{\hat{W}_Y} \times \mathbf{r} \]

Than, the linear coordinates \(X\), \(Y\) and \(Z\) are equal:

\[ X = -\mathbf{Q} \cdot \mathbf{\hat{W}_X} \]
\[ Y = \mathbf{Q} \cdot \mathbf{\hat{W}_Y} \]
\[ Z = \mathbf{Q} \cdot \mathbf{\hat{W}_Z} \]

The angular coordinate \(B\) means rotation about \(Y\) axis and corresponds to root angle \(\delta_M\) and is given by:

\[ B = \sin^{-1}(-\mathbf{P}\mathbf{O} \cdot \mathbf{\hat{W}_X}) \]

For the Gleason system, the \(C\) axis means the cutting velocity and the rotational angle does not depend on rotational position of the work-piece. The \(C\) axis is very important for Oerlikon/Klingelnberg system, where the relation between rotational position of cutter and work-piece exists. Thus, the reciprocal rotational position of cutter and work-piece is determined by the following functions:

- for cutter head angular position:
  \[ \omega_C = \sin^{-1}(-\mathbf{r} \cdot \mathbf{\hat{W}_Z}) \]
- for work-piece angular position:
  \[ \omega_{PO} = \sin^{-1}(-\mathbf{p} \cdot \mathbf{\hat{W}_Y}) \]

Rotation of the cutter head with number of blade groups should be synchronous with number of work-piece teeth. The rotational velocity of the cutter and work-piece does not have any relation and it is the cutting speed only.
5. CONCLUSIONS

The CNC spiral bevel gear machine that is controlled in the 6-axis has the common basic technological parameters with the conventional machine. It is very important, due to the fact that computer calculations for the conventional machines and particularly the basic technological settings are the grounds to determine relations in all 6 axes. The basic technological settings are the input data to CNC controller. Even though the cutter axis is parallel to the Z axis and perpendicular to the XY plane, the continuous transformation of the coordinates allows the possibility of using the technological methods with cutter tilt. The CNC machines allow cutting the spiral and hypoid bevel gears independently of a cutting system such as Gleason or Klingelnberg/Oerlikon.

ABSTRACT

This paper presents the issue of Corporate Social Responsibility with its characteristics, assets, advantages and disadvantages. It analyses stakeholders, their importance and possibilities of their engagement as a factor of the performance and competitiveness of a company in the 21st century. This paper also seeks to answer the question: Why is CSR important and why follow requirements of CSR?

1. INTRODUCTION

The concept of CSR was established in the 1950s. It is a way of managing a company and making relationships with partners which contributes to improving the reputation and credibility of a company. The European Union supports CSR activities in the Europe. This issue has been worked on since the 1990s. The European Union uses CSR as a tool for achieving tenable and acceptable growth.

Corporate Social responsibility can be defined as a voluntary commitment on the part of a company to behave responsibly with the respect to its surrounding environment and the society within which it operates. The company conducts business in accordance with high ethical standards, builds good relationships with its business partners, cares for its employees, supports its local region, tries to minimize any negative impact on the environment from its operations.

CSR promotes the active engagement of stakeholders in the company’s decision-making processes. The term stakeholders is used to describe all parties that are involved with the company. They include people or groups of people operating both inside and outside of the company, such as owners, investors, employees, customers, business partners, the local community, etc.

2. CORPORATE SOCIAL RESPONSIBILITY

2.1. CONCEPT OF CORPORATE SOCIAL RESPONSIBILITY

CSR is based on three fundamental principles. They are economic, social and environmental. Each part of CSR contains a lot of different activities depending on the type of enterprise and the requirements of stakeholders.

---

1* Marcela Srchová: Tel.: +420 377 638 464; Fax: +420 377 638 402; E-mail: srchova@kpv.zcu.cz
The main features of CSR are:
- triple-bottom-line – economic, social and environmental,
- voluntary – all activities are done voluntarily,
- stakeholders dialogue – integration of all participants,
- long-term period – all activities are done over a long-term period,
- credibility – increasing company credibility.

### 2.2 Advantages of Corporate Social Responsibility

Responsible behaviour is advantageous, brings a lot of benefits, especially non-financial, which are also very important for successful enterprise.

<table>
<thead>
<tr>
<th>CSR advantages</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Higher reputation of company, better company image</td>
</tr>
<tr>
<td>• Higher attraction for investors</td>
</tr>
<tr>
<td>• Good reputation and strong position in market</td>
</tr>
<tr>
<td>• Distinguish from rivals</td>
</tr>
<tr>
<td>• Increasing employees’ productivity and loyalty</td>
</tr>
<tr>
<td>• Attraction for quality and talented potential employees</td>
</tr>
<tr>
<td>• Decreasing expenses on risk management</td>
</tr>
<tr>
<td>• Direct financial saving – ecological behaviour</td>
</tr>
<tr>
<td>• Better relationships with local society and public institutions</td>
</tr>
</tbody>
</table>

CSR does not bring advantages only to big companies, small and medium sized companies can also gain some advantages. They are: easier recruitment of employees and business partners, good public relations, possibility of getting contacts and information from society and from main business partners.

### 3. Stakeholders

#### 3.1. Classification of Stakeholders

A company has three kinds of stakeholders: organizational stakeholders (internal to the company) and economic and societal stakeholders (external to the company).

*Organizational Stakeholders*
First, stakeholders exist within the organization. The business functions and practices that affect organizational stakeholders are presented from a CSR perspective. Examples of organizational stakeholders are stockholders, employees, and managers.

**Economic Stakeholders**

Second, they serve as the interface between the organization and its larger social environment. Not only do the issues in this section affect the financial aspects of the organization, they create bonds of accountability the firm and its wider operating context. Examples of economic stakeholders include consumers and creditors.

**Societal Stakeholders**

Third, topics that affect societal stakeholders determine the business environment in which the firm operates. Examples of societal stakeholders include government agencies and regulators, communities, and the environment itself.

In this figure you can see the stakeholder classification.

![Figure 2: Stakeholder Classification](image)

This model is not limited to for-profit organizations and can be applied equally to governments and nonprofits. Economic stakeholders serve as the accountability interface between any organization and the society within which it operates. Among businesses, the accountability mechanism is profit and loss. If a company fails to make a profit over the long term, it will be unable to remain in business. For democratic governments, the accountability mechanism is twofold. The campaign contributions that finance the democratic process and the votes of stakeholders (taxpayers), which determinate the outcome. And for nonprofits, the accountability mechanism is the organization’s ability to generate sufficient operational funds by justifying its continued existence to economic stakeholders.

Without these economic interfaces, organizations lose their mechanism of accountability and, therefore, their legitimacy over the long term. This is true regardless of whether the organization is a business, government, or nonprofit.

### 3.2 Importance of Stakeholders

The systematic and regularized involvement of key stakeholders gives the business numerous advantages, [4]:

**Innovative Environment:** A continuing dialog with stakeholders represents a valuable tool for the prediction of new trends and possible areas of interest to the business. It allows the company to better understand the complexity of the business environment and current market trends, helping it to properly put together its future strategic plans.
Risk Management: A dialog with external parties can often warn a business about potential future risks – this is especially true if the company is able to maintain a relationship with those stakeholders having a negative perception of the company.

Mutually Beneficial Relationships: Face-to-face contact and the ability to maintain a close relationship with stakeholders is the best way to build mutual trust between the company and its key stakeholders.

Setting of Objectives and Performance Monitoring: An outsider’s perspective allows the company to properly set out its objectives and evaluate its actual performance.

Access to Information: Strong and close relationships with its stakeholders can be a valuable source of information for the company.

3.3 Engagement of Stakeholders

An explanation and overview of the roles played by the stakeholders throughout the four stages of the CSR implementation process (planning, execution, evaluation and improvement) helps to better understand how important it is to get the stakeholders involved in the decision-making processes of one’s business, [5]. The roles are briefly outlined here and showed at the following figure:

Planning
During the planning stage, stakeholders can help us to understand the respective economic, social and environmental impacts of our company’s actions and help us choose the right CSR strategy for our business.

Execution
Stakeholders play an important role in our business’ execution of our CSR strategy by helping us to define and act upon our company’s commitments in the area of corporate social responsibility.

Evaluation
Stakeholders are an essential part of the monitoring and reporting of our business' performance. They are included in our selection of performance indicators and provide us with feedback on our performance in the different CSR areas.

Improvement
Our stakeholders contribute to the shaping of ideas for improving our existing CSR strategy.

![Figure 3: Engagement of stakeholders](image-url)
4. IMPLEMENTATION OF CSR

Many companies are already engaging in activities in the area of customer and employee care, community support and environmental protection. These activities can serve as a good starting point for the development of a more strategic approach to Corporate Social Responsibility.

When implementing the CSR concept, it is important to have a systematic approach and to take the following into consideration with the respect to your company its:

- mission statement,
- corporate culture,
- area of specialization and area of business,
- business strategy,
- environmental profile,
- risk profile,
- operating conditions.

The following implementation diagram is based on the well-known PDCA concept:

- Plan = plan ahead.
- Do = execute your plan.
- Check = evaluate the results.
- Act = act on the results by trying to improve.

![PDCA concept diagram](image)

5. CSR COMMUNICATION

There are many communication tools and methods that the company can use when providing communications about its socially-responsible behavior to others. Some of these are highly affordable and take a minimum of effort, [6].
Table 2 Tools of communication CSR

<table>
<thead>
<tr>
<th>Tools of CSR communication</th>
</tr>
</thead>
<tbody>
<tr>
<td>• CSR report</td>
</tr>
<tr>
<td>• Internet / Intranet</td>
</tr>
<tr>
<td>• Internal / external newsletter and magazines</td>
</tr>
<tr>

<tr>
<td>• Product designations (employer of the year, responsible enterprise)</td>
</tr>
<tr>
<td>• Awards and recognition</td>
</tr>
<tr>
<td>• Active communication with the media (press releases, conferences, announcements)</td>
</tr>
</tbody>
</table>

Once the company has initiated a collaborative relationship with its stakeholders and started to engage in activities that are part of its overall CSR strategy, it is time to let the surrounding community and also the company’s own internal community know about its initiatives in the area of corporate social responsibility. As a first step, the company has to make sure that its employees and partners are supportive of the company’s efforts in this area. In order to make this happen, the company has to thoroughly explain to them what, how and why certain types of CSR activities are being undertaken. The company’s external stakeholders also need to be properly informed about these CSR efforts because this is the only way in which the company will be able to set itself apart from its competitors in the eyes of these external parties. Let the others know that you are a socially-responsible business. This information should be appropriately communicated, reflecting the activities and initiatives in which your company is involved.

Regularly communicating information about the company’s socially-responsible behavior can provide the company with a number of advantages. They are briefly outlined in the following table.

Table 3 Advantages of CSR communications

<table>
<thead>
<tr>
<th>Advantages of CSR communications</th>
<th></th>
</tr>
</thead>
</table>
| Transparency                       | • Provide others better information about the company’s CSR activities.  
                                      | • Make the company and its business more transparent. |
| Better control over CSR activities | • Compare proclaimed CSR commitments with what is actually taking place.  
                                      | • Identify weaknesses in its corporate CSR strategy. |
| Involvement of stakeholders        | • Strengthen the position.  
                                      | • Involvement of stakeholders in company decision-making processes |
| Non-commercial partnerships        | • Promote non-commercial partnerships between for-profit, governmental and nonprofit organizations. |
6 SUMMARY

There are a lot of argument for Corporate Social Responsibility. CSR broadly represents the relationship between a company and the principles expected by the wider society within which it operates. It assumes businesses recognize that for-profit entities do not exist in a vacuum and that a large part of their success comes as much from actions that are congruent with societal values as from factors internal to the company.

CSR is a rational argument for businesses seeking to maximize their performance by minimizing restrictions on operations. In today’s globalizing world, where individuals and activist organizations feel empowered to enact change, CSR represents a means of anticipating and reflecting societal concerns to minimize operational and financial limitations on business.

Summing the moral and rational arguments for CSR leads to an economic argument. To incorporate CSR into operations offers a potential point of differentiation and competitive market advantage upon which future success can be built, besides avoiding moral, legal, and other sanctions.

CSR influences all aspects of a business’s day-to-day operations. Everything an organization does interacts with one or more of its stakeholders groups. Companies today need to build a watertight image with respect to all stakeholders. CSR is an argument of economic self-interest for business. CSR adds value because it allows companies to reflect the needs and concerns of their various stakeholder groups. By doing so, a company is more likely to retain its societal legitimacy and maximize its financial viability, over the long term.

ABSTRACT

Outsourcing, joint ventures, and cross-border collaborations have led to work environments geographically distributed across organizational and national boundaries. Targeting the distributed environment, the Web has been widely used for development of collaborative applications supporting dispersed working groups and organizations, because of its platform, network and operating system transparency, and its easy-to-use browser interface. The objective of this research is to develop an innovative Web-based distributed process planning system (Web-DPP) for machining operations. Our approach tries to engage a dispersed working group in a collaborative environment, allowing the team members to share real-time information through the Web-DPP. This paper presents both the system design specification and the latest development of this system.

1. INTRODUCTION

Today’s manufacturing systems are required to be flexible and adaptive to unpredictable changes in a dynamic environment, where manufacturing operations may be rearranged or replaced upon the changes. Such manufacturing systems must contain collaborative and intelligent entities that can adaptively adjust themselves so as to achieve a global system objective. As a constituent component of the manufacturing systems, the entity for process planning is required to be responsive and adaptive to the rapid adjustment of production capacity and functionality. Unfortunately, traditional process planning methods are time-consuming and error-prone, if applied to such a changing environment. Therefore, adaptive and intelligent process planning has been a hot topic for the last decade. A number of approaches have been reported in the literature, trying to solve the challenging problem in process planning. Recent efforts include object-oriented approach [1], Petri net-based approach [2], neural network-based approach [3], knowledge-based approach [4], genetic algorithm-based approach [5], and feature-driven approach [6]. These reported approaches and their combinations have been applied to several specific problem domains, such as setup planning [7], process sequencing [8], tool selection [9], cutting parameter selection [10], and tool path planning [11].

Despite the achievements in solving complex decision issues in process planning, these reported approaches and systems are limited to static problems through decisions made in advance. Their adaptability to unpredictable changes on shop floors remains insufficient. Most process planning systems available today are centralised in architecture, and off-line in data processing. It is difficult for a centralised off-line system to make adaptive decisions, in advance, without knowing actual run-time conditions on the shop floors. To be responsive to sudden changes, a distributed and adaptive approach is considered suitable for handling the dynamic situation, especially for job shop operations. In this paper, we propose a Web-based distributed process planning (Web-DPP) approach to solving the problems.

* Corresponding author: Tel.: +46 (0500) 44-8519; Fax: +46 (0500) 44-8598; E-mail: lihui.wang@his.se
The objective of the Web-DPP is to improve the performance when planning machining operations on shop floors. It uses a two-layer structure – *supervisory planning* (SP) and *operation planning* (OP). The supervisory planning focuses on high-level machining sequence generation, while the operation planning focuses on machine-specific working step planning and execution. More details of the Web-DPP concept are introduced in Section 2, followed by the architecture design in Section 3. Section 4 presents in detail the system analysis of the Web-DPP in IDEF0, which is implemented in Section 5. Finally, in Section 6, our research contributions and future work are summarised.

### 2. WEB-DPP CONCEPT

Figure 1 illustrates our long-term research activities of distributed process planning, dynamic scheduling, real-time monitoring and remote control in a shared cyber workspace, where Web-DPP is the focal point of adaptive decision making based on monitoring information and available resources from scheduling.

Process planning is the task that transforms design information into manufacturing processes and determines optimal sequence for machining. A process plan generally consists of two parts: *generic* data (machining method, machining sequence, and machining strategy) and *machine-specific* data (tool data, cutting conditions, and tool paths). A two-layer hierarchy is, therefore, considered suitable to separate the generic data from those machine-specific ones in Web-DPP. This concept is shown in Figure 2.
Other than SP and OP, machining features and function blocks are two crucial concepts adopted in the Web-DPP. They carry the machining process information and go through a number of functional modules of the system. As shown in Figure 2, machining features are first created and maintained as part of product data by a machining feature-based design system (for non-feature-based design systems, a third party utility tool is needed for features recognition). The tasks of Web-DPP are divided into two groups and accomplished at two different levels: shop-level supervisory planning and controller-level operation planning. The former focuses on product data analysis, machining feature decomposition, setup planning, machining process sequencing, jig/fixture selection, and machine selection. The latter considers the detailed working steps for each machining operations, including cutting tool selection, cutting parameters assignment, tool path planning, and control code generation. Between supervisory planning and operation planning, scheduling functions can be integrated by means of function blocks. Because of the two-level structure, the decision-making in Web-DPP becomes distributed in terms of (1) timing (supervisory planning in advance vs. operation planning at runtime) and (2) location (supervisory planning in one office workstation vs. operation planning by many machine controllers). The separation of decisions also makes the high-level process plans generic and portable to alternative machines. In other words, since a final process plan is generated adaptively yet at runtime by CNC controllers, there is no need to generate redundant alternate process plans.

### 3. WEB-DPP SYSTEM ARCHITECTURE

The Web-DPP is not limited to process planning. It also covers process plan dispatching and execution monitoring at shop floor and machine levels. Such functionalities are designed into the system architecture as shown in Figure 3, where supervisory planning, execution control and operation planning are the three major components. The execution control looks after the dispatching of jobs while interfacing with scheduling and monitoring modules to retrieve the latest information of availability of resources and status of machines. In this research, we neglect the feature-based design and feature recognition at product design stage, based on an assumption that machining features are already available in product data. They are either created directly by using a feature-based design system or recognised by a third party feature recognition solution.

**Figure 3: System architecture of Web-DPP**

During supervisory planning, a generic setup plan can also be created by grouping machining features according to their tool access directions. The generic setup plan is for 3-axis machines. Necessary setup merging for 4- or 5-axis machines is conducted during the execution control and before setup dispatching to best utilise the capability of the machines. Decision making at different stages is supported by networked knowledge bases and databases, whereas the latest monitoring information is made available to the execution control for directing dynamic scheduling and dispatching machining jobs.
4. System Analysis

The system analysis work of the Web-DPP is carried out using IDEF0. The three core components of the Web-DPP shown in Figure 3 are modelled in IDEF0 in Figure 4, together with their inter-relationship and data flow, where M1 to M5 represent human, computer, network, security and machine, respectively. Meta function blocks (MFBs) are used in this research to encapsulate machining sequences (of setups and machining features), and are the output of supervisory planning. As its name suggested, an MFB only contains generic information about process planning of a product. It is a high-level process template, with suggested cutting tool types and tool path patterns, for subsequent manufacturing tasks. Execution function blocks (EFBs) are the function blocks that are ready to be downloaded to a specific machine. Basically, an EFB can be created by instantiating a series of MFBs associated with a task. Each manufacturing task corresponds to its own set of EFBs, so that the monitoring functions can be conducted for each task unit. The structure of an operation function block (OFB) is as same as an EFB. However, OFB specifies and completes EFB with more detailed, machine-specific data about machining processes and operation sequences. Moreover, operation planning module can override and update the actual values of variables in the EFB, so as to make it locally optimised and adaptable to various events happened during machining operations. We use two different terms of EFB and OFB to distinguish a given function block, because they are two separate entities with different level of detail in contents, fulfilling different level of execution, residing in different systems, and moreover, they may be deployed in physically distributed CNC controllers.

4.1. Supervisory Planning

An incoming main manufacturing plan (from a high-level production planning system) triggers the SP to generate a machining sequence plan of a given product. Feature-based reasoning is applied in the SP with considerations of only regular manufacturing resources (3-axis milling machines, regular fixtures and cutters, etc.) and the support of general knowledge base of machining technology and constraints. The generated machining sequence plan is passed to a function block designer and packed as networked meta function blocks. Details of the internal structure and data flow of SP are depicted in Figure 5. Within the SP, the function block designer is responsible of defining new function block types, specifying task-specific algorithms for each function block type, and mapping machining features to MFBs according to the generated machining sequences.

4.2. Execution Control

Scheduling information and monitoring events are integrated into and handled by the execution control module, which makes execution control an important integration point of data, activities and decision makings of the Web-DPP.
system. The functionalities of execution control include setup merging (for 4- and 5-axis machines), event handling, function block dispatching, and process monitoring as shown in Figure 6.

4.3. OPERATION PLANNING

OP is a real-time execution environment of operation function blocks. It not only specifies and optimises the process plans received from the SP (cutting tool selection, machining sequence optimisation, machining parameters selection, and tool path generation), but also executes the OFBs one by one, dynamically, in an explanation engine (Executor). In this way, the operation planning process on a machine controller can be truly adaptive, which means it can dynamically modify its process plans according to the dynamics of the actual machining process. Details of the OP are given in Figure 7.
5. SYSTEM IMPLEMENTATION

The Web-DPP is designed to use the popular browser-server architecture and VCM (view-control-model) design pattern with built-in secure session control. The proposed solutions for meeting both the user requirements of rich visual data sharing and real-time constraints are listed below.

- Based on Web B/S architecture
- Using interactive scene graph-based Java 3D models based on XML-style file format
- Providing users with browser-based thin-client graphical user interface for distributed process planning
- Deploying major planning and control logics in a secure application server

![Figure 7: IDEF0 model of operation planning](image)

![Figure 8: Three-tier architecture for Web-DPP implementation](image)
The mid-tier application server handles security concerns and control logics, including session control, viewer registration, data collection/distribution, and algorithm invocation. A central session manager is designed to look after the issues of user authentication, session control, session synchronisation, and sensitive data logging. All initial transactions need to pass through the session manager for access authorisation. A registrar is designed to maintain a list of subscribers with the requested data access. The http streaming protocol is chosen for the best combination between applets and servlets used for system implementation. Another server-side component called data accessor is designed to separate the logical and physical views of data. It encapsulates JDBC (Java Database Connectivity) and SQL codes and provides standard methods for accessing data (Java 3D models, knowledge base of the devices, or XML-style documents). Figure 9 depicts the system implementation package diagram, and Figure 10 shows one snapshot of the system for web-based distributed process planning.

![Figure 9: Implementation package diagram of Web-DPP](image)

![Figure 10: Web-DPP for distributed process planning](image)
6. CONCLUSIONS

This paper presents a Web-based approach for distributed process planning (called Web-DPP) in a dynamic and uncertain manufacturing environment, particularly for job shop machining operations. The advantage of such a system is the adaptive decision making to unpredictable changes. The system is designed to separate generic process planning information from machine-specific ones. The novelty and contributions of this research are summarised below.

• Two-layer distributed system architecture for distributed decision making,
• Machining feature based reasoning for machining sequence determination,
• Function blocks to encapsulate machining sequence for controller-level operation planning, and
• Execution control linking process plans with monitoring and scheduling for job dispatching.

Our future work will focus on algorithm development, functionality enhancement and testing through real-world case studies. Integration with a third-party scheduling system and a monitoring system is also under development, the results of which will be reported separately.

ACKNOWLEDGEMENT

The Web-DPP research is supported by the Natural Sciences and Engineering Research Council of Canada.

ABSTRACT

Nowadays, the global market requires shorter life cycles and variety of products to satisfy customer’s demands. Many manufacturing companies need to design and implement manufacturing systems rapidly to enhance global competitiveness. For these reasons, VR (Virtual Reality) technology has been used principally for system design and process development of many companies in the manufacturing industry over the last few years. However, VR based digital manufacturing methods and software require perfect 3D models of whole manufacturing system in the virtual environment to implement and simulate target systems. This means that modelling tasks for new system configuration increase useless expenses and efforts. AR (Augmented Reality) technology as a new man-machine interface has been introduced by not only computer science companies but also some manufacturing companies. AR technology superimposes required virtual objects on the real-time image of the physical manufacturing environment. Therefore, the modelling time and cost for new manufacturing system can be dramatically reduced by using AR technology.

In this paper, the architecture of the developed AR software for the manufacturing system is introduced. Moreover, the methods such as a multi-marker coordinate system, a threshold image, a clipping plane for virtual objects, and so on, are proposed to generate the operation program for the manufacturing system. Base on these methods, the test bed of the automobile spare tire inserting system is configured as a 5X-reduced scale and the operation program for spare tire inserting is generated.

1. INTRODUCTION

In recent years, the computer graphic technology has been growing dramatically with computer industry growth. In this exigent situation, the research of VR (Virtual Reality) and AR (Augmented Reality) technology which describe realistic scenes is performing actively [1-5]. Moreover, not only computer science companies but also many manufacturing companies have been studying about VR technology, because the global market requires a variety of product and shorter life cycle to fulfill the diverse demands of customers to survive in the turbulent and competitive market.

In the case of VR based digital manufacturing technologies, it can be used to analyze static and dynamic system behavior at all stages of manufacturing system configuration as an advantage [6-7]. To put it the other way around, the modeling work requires much expenses and efforts, because the whole system has to be modeled. Some manufacturing companies which realize the weaknesses of VR based digital manufacturing technologies have been studying AR technology. AR technology can remarkably reduce the modeling work, because it uses the real environment to design and plan manufacturing systems [8-9].

The ambitious goal of AR is to create the sensation that virtual objects are present in the real world. To achieve the effect, software combines VR elements with the real world. Obviously, AR is most effective when virtual elements are added in real time. Because of this, AR commonly involves augmenting 2D or 3D objects to a real-time digital video image. The simplest example of visual AR is overlaying a 2D image on digital video. However, it is also possible to

* Corresponding author: Tel.: (82) 52-2592294; Fax: (82) 52-2591680; E-mail: phosk@ulsan.ac.kr
add 3D objects. Generally speaking, adding a 3D object to real-time video makes for a more impressive demonstration of AR technology [2].

AR technology is consisted basically of three modules which are image processing, tracking and rendering. The image processing module has to support the various types of the image data and can process the lots of image data. The image processing module sends the obtained image data to the tracking module. And the rendering module performs image superimposition. Among these three modules, tracking and registration problem is one of the most fundamental challenges in AR research today. The precise, fast, and robust tracking of the observer, as well as the real and virtual objects within the environment, is critical for convincing AR applications. Because of this reason, much research effort is spent to improve performance, precision, robustness, and affordability of tracking systems. Besides tracking, real-time rendering is also basic element for augmented reality. Since AR mainly concentrates on superimposing the real environment with graphical elements, fast and realistic rendering methods play an important role [3].

In this paper, Chapter 2 describes the design of AR system which can be used rapidly and easily at the process of manufacturing system configuration. The scope of the development for AR system, the architecture of AR system, the configuration of the user interface and the functions of the user interface etc. are introduced. Chapter 3 introduces the methods of software implementation based on the basic design. The basic structure of image processing and the tools for implementation of image processing module are introduced. And the information which is needed to track the coordinate data, moreover the methods for coding by using C++ is described for tracking and rendering techniques. Chapter 4 describes the usability of developed AR system to apply to the automobile spare tire inserting system.

2. DESIGN OF AUGMENTED REALITY SOFTWARE FOR MANUFACTURING SYSTEM

2.1. THE SCOPE OF THE DEVELOPMENT

In this research, the software development activities of AR for the manufacturing system consist of requirements analysis, specification, software design, implementation, testing and maintenance. These processes were performed recursively with correction of each step. In the requirements analysis step, the general requirements were gained from the client and the analysis of the scope of the development was determined clearly. The analysis document of requirements includes the flow chart of overall tasks, the systematical analysis information of functions, activities and data. The concise software development scope is as follow.

1) The user selects the camera devices which are connected to computer by the device enumeration dialog box.
2) The user inputs the each number and total count of markers.
3) The 3D objects (.wrl) are loaded to use for the parts of the manufacturing system.
4) After markers and virtual objects setting, the display device shows superimposition of real-time images.
5) The translation, rotation and scale data of each virtual object can be controlled by the user.
6) The clipping plane for collision detection can be created and also can be controlled by the user.
7) The visible and invisible functions for the images and virtual objects are able to operate.
8) The marker tracking start and stop functions can be used during the software activity.
9) The user can confirm the information about program activation by the message boxes.
10) The information of each marker and each virtual object data can be removed by the user.

Based on the specification document of requirements analysis and the three basic modules which were introduced at chapter one, the auxiliary functions can be supplemented for manufacturing environments. In this paper, the convenient functions which are clipping planes for collision detection and threshold control panel for the dim condition. And these functions support the user to work efficiently. Figure 1 illustrates the architecture of AR system. And the core development tool is MFC (Microsoft Function Class) based on C++.

The image data from a camera device is processed in video interface for the marker tracking. The video interface converts the video image stream into non-calibrated RGB24 image. Then the marker tracking function calculates continuously coordinate data of the markers to detect location of each marker. The basic coordinate system for positioning virtual objects is established through the matching procedure between the information of the marker database and the input data of the user interface. The rendering function performs generating and removing of virtual
objects with calculated coordinate data. Also, the coordinate transform of virtual objects is executed by using three translations data, three rotations data and three scales data.

Figure 1: Architecture of AR System

2.2. THE CONFIGURATION OF THE USER INTERFACE

The user interface designed detailedly based on basic functional analysis of whole system as shown in Figure 2.

Figure 2: Layout of user interface

1) The menu bar
2) The display plane for the render scene
3) The camera device controlling panel
4) The marker information setting panel
5) The virtual object controlling panel
6) The tracking function panel (start/stop)
7) The message enumerating panel to check program state
The menu bar consists of the functions which are performed from the right side panels. The display plane is the drawing board for superimposition of scenes and it draws 3D objects and 2D images from the camera. The user can confirm the list of connected camera devices by using the camera control panel and can change the camera properties easily. The marker information setting panel is used to input the information of the marker such as the size of the marker, the number of the marker, the total count of the markers to use and so on. And it is also used to control the marker information. The virtual object controlling panel is used to load the 3D objects for rendering and to control. The tracking function panel is used to control start and stop for the position tracking function. The message enumerating panel is helpful for user’s activities to check program state.

3. IMPLEMENTATION OF AUGMENTED REALITY SYSTEM

3.1. OBTAINMENT AND CONVERSION OF REAL-TIME IMAGE DATA

Precision and accuracy of target tracking depend on the image resolution of the camera device. USB Web Camera which has low resolution is used generally for experiments at a large number of laboratories. However, ordinary manufacturing system requires the tasks with high precision and accuracy. Because of this reason, the digital video camcorder that is connected to computer through the IEEE 1394 interface was used. OpenCV is the prevalent open source vision library suitable for computer vision applications [10]. However OpenCV does not support digital video image type. To solve this problem, high resolution buffer is obtained by using Microsoft DirectShow technology in this research. The rapid image processing is possible by using various filters. It is a representative advantage of DirectShow [11]. Also well-composed filters are figured out readily through the GraphEdit which is the utility of DirectShow. In this paper, device filter, preview filter, digital video supporting filter, SampleGrabber filter and Video Renderer filter are used to gather RGB24 image data. Moreover the obtained image buffer is converted into IplImage structure of OpenCV. This technique has the ability to access readily and offers the efficient method which converts RGB24 image data into different image type. The last image type is BGR24. Figure 3 depicts whole image processing step structure.

![Figure 3: Image obtaining and conversion steps](image)

3.2. POSITION TRACKING OF TARGET MARKERS

The position tracking of the target marker is the core technology that is determinant for precision and accuracy of AR technology. For tracking target markers, many methods, such as mechanic, magnetic, and optical are examined. Here, the optical method is widespread due to its high precision among the tracking methods. The camera device reads real-time video streams to generate see-through effects on the display equipment. Then edge detection is performed by thresholding with constant value. After this step, the information of detected marker is used to track the local coordinate in the centre of the marker by using matrix calculation.

There are some pose estimation algorithms as the robust planar pose algorithm, the fast pose estimation algorithm, and so on. These algorithms were ported to C++ added to the open source libraries as AR Toolkit, ARToolkitPlus, ARTag, and so on [1-3], [12]. In this paper, ARToolkitPlus tracking function that includes improved pose estimation...
Implementation of Automobile Spare Tire Inserting System using Augmented Reality

quality with less jitter and improved robustness was used to track coordinate system. The important function for using is rppGetTransMat() [1], [13]. This function performs matrix parameters translating to transmit the coordinate data to the rendering module. For this achievement, codes of the matrix parameters translating function and of the tracking function were generated.

The virtual object can be superimposition on the real scene by using each ID-based single marker. Moreover the multi-marker which has one local coordinate system can be used to track. Every single marker size was set 100mm and the user can change the marker size as required at the user interface. The multi-marker size can be changed in the designated data file.

3.3. IMPLEMENTATION OF VIRTUAL OBJECTS LOADING AND SUPERIMPOSITION OF SCENES

The superimposition of scenes is performed by using the obtaining image data, the tracking positions and the virtual objects. The system requirement of the hardware is prime concern to draw the scenes into viewing rectangle of the user interface. Therefore, the overall specification of the hardware as a graphic device, CPU and memory devices have to be high. The high specification of the hardware prevents jitter and lag of the superimposition scenes [14]. Also the VRML (Virtual Reality Modeling Language) object files decrease the software overhead and improve the problems of jitter and lag status. All things considered, the object control panel can load text files (.txt) which include the coordinate information of the virtual object based on rearrangement coordinate matrices. And the data structure including the two-dimensional array was designed for each object rendering on the marker. The data structure has the information of each marker number, visible/invisible, object number and translation-rotation-scale of each object as shown in Figure 4. These processes are performed by using OpenGL open source graphic library [15].

![Figure 4: Data structure including two-dimensional array and the implementation codes of the data structure](image)

This information can be controlled through the object control panel. The translation unit value of the virtual object is 1mm and the rotation unit value of the virtual object is 1°. In the case of scaling, required input value through the user interface is 100 when the side length of the square marker is 100mm. If the side length of the square marker is 40mm, the input value must be 40 to satisfy 1:1 scale between the viewing object and the modeling object.

3.4. IMPLEMENTATION OF AUXILIARY TOOLS

The clipping planes can be generated to check the collision between the virtual objects and to ensure the inside area of the virtual objects. The gClipPlane() function of OpenGL was used to generate clipping planes. Therefore, the user can generate 6 planes and can use them at the same time [15]. The normal vector of the clipping plane is derived from the equation of plane to achieve same effect as object controlling. The equation of plane is derived by using one known normal vector and one known point in the three axes generally. However, the normal vector of the clipping plane is derived by using one known point O(0, 0, 0) and three angles which were inputted by the user as shown in Figure 5 and Equation (1). And the point O(0, 0, 0) is always used to calculate the equation as the known point.
\[
\begin{align*}
a &= \cos(\theta_y)\cos(\theta_z) \\
b &= \cos(\theta_x)\cos(\theta_z) \\
c &= \cos(\theta_x)\cos(\theta_y)
\end{align*}
\]

(1)

where, \(\theta_x\), \(\theta_y\), \(\theta_z\) = three known angles

Through the derived normal vector decides the direction of the plane and the plane can be rotated between -180° and 180° by the user’s activity. In this case, both the translation and scaling were not considered.

The generated clipping plane does not have visualization feature. Because of this problem, there is the difficulty to recognize the location of the clipping plane in the virtual space. To solve this problem, the virtual object of the grid plane is created basically and it is matched with the clipping plane at the same time as shown in Figure 6.

The manufacturing field has poor light condition. For this reason, the optical marker cannot be recognized easily. To supplement this handicap, threshold value is controlled through the panel. The function of controlling threshold value returns selected pixel value of the binary image from 0 to 255. To control the threshold value, the functions of OpenCV are added as a cvThreshold [10].

4. Reconfiguration of Manufacturing System based on Augmented Reality

4.1. Component Modeling Work for System Configuration

The developed AR system is applied to the reconfiguration process of the automobile cockpit module assembly system which is the test bed for the real manufacturing system [9]. The target system is the automobile spare tire inserting system. Almost new components have to be remodeled. However, the air finger, the connecting part of the
robot and the ball screw are changed partial dimension except overall outer shape. In this case, the existing facility of the test bed is used as it is. The gripper and air finger which perform assembly work, the automobile body for transfer, and the jig/fixture for the automobile body, the encoder and coupling for the synchronous velocity are continuous parts of the virtual object structurally. And these parts perform similar work. Therefore, the each 3D model of them is generated. And the spare tire, the mount for the robot and the jig/fixture of the spare tire are modeled individually. Moreover, the auxiliary tools for collision-free between the peripheral unit and for accurate assembly work were modeled. The centre datum line was generated individually to match between the assembly part of the automobile body and the spare tire. And the approach path was set and was modeled to avoid collision between the robot and the automobile trunk. The operator is able to perform generating of the robot operation program precisely by using these auxiliary tools. Figure 8 shows the 3D models for system configuration.

**4.2. Setting Coordinate Systems based on Markers**

To perform superimposition of the generated 3D models, the coordinate system for positioning virtual objects has to be established. The Generated 3D models are divided into two groups. The first group has dynamic motion and the second group does not have movement. The spare tire, the gripper and air finger which perform assembly work require independent one coordinate system (coordinate system No.1). Also the centre datum line of the spare tire for assembling serviceability used the coordinate system No.1. The coordinate system No.1 has to be mounted on the end of the robot gripper. Moreover, the system should be seen in every direction due to free movement of the robot. Therefore, the coordinate system No.1 which has several markers was manufactured in the structure of a box type. And the automobile body and its jig/fixture on the carriage part require independent one coordinate system (coordinate system No.2), because the carriage plate influences to the automobile body and its jig/fixture. The centre datum line of the automobile body and the path of assembly work used the coordinate system No.2. In addition, one marker which considers the position of the camera device was established. The encoder, the coupling, the mount for the robot and the jig/fixture of the spare tire are fixed components and they have collision-free during assembly work. So these components use one coordinate system (coordinate system No.3). Figure 9 illustrates the generated coordinate systems for configuration of the spare tire inserting system.

Figure 8: Generated 3D models for spare tire insert system

Figure 9: Generated 3D models for spare tire insert system
4.3. GENERATING OPERATION PROGRAM FOR SPARE TIRE INSERTING SYSTEM

The test bed of the automobile spare tire inserting system is configured as a 5X-reduced scale. The operator generates the robot operation program with two cameras. One camera is set at the side of the test bed and the other is set at the behind of the test bed. The completeness of the generated operation program was proven by applying it to the conventional assembly station. The boundary conditions, such as the position tolerance range within 5~10 mm, were fulfilled.

5. SUMMARY

In this paper, the AR system which can be used at the manufacturing system was developed based on general software development method. The fundamental functions as the video interface, the tracking and rendering were implemented. And the manufacturing field condition-oriented auxiliary functions were added.

The function of generating clipping plane and controlling for precision and accurate work was used effectively during generating robot operation program. And the threshold value control function has similar effectiveness. These results attest functionality of the developed AR system which has high usability when the manufacturing system configuration is performed.

The function of the distance measurement between the virtual objects, and the dynamic movement function of the virtual objects are required after this research. Also, not only digital video camcorder but also CCD camera which is used generally in the manufacturing industry needs to be able to use with AR system.

Design of Collaborative BOM Management System for Small and Medium Enterprises

Bo Hyun Kim*, So Young Jung, Jae Yong Baek, Seok Woo Lee, and Hun Zong Choi

Digital Collaboration Service Center
Korea Institute of Industrial Technology
Ansan, Kyunggi, 426-171, Korea

ABSTRACT

Most commercial PDM (product data management) systems, which have been released recently by overseas famous software vendors, are still expensive and heavy to apply to small and medium enterprises (SMEs) organizing a cooperative consortium. Proposed in this paper is the architecture and functions of a light and collaborative design management system called collaborative BOM (bill-of-material) management system (cBOM-MS). The cBOM-MS consists of BOM navigator which is a client/server based system and supports core functions to manage BOM in each company and collaborative BOM (cBOM) portal which is a web based program and provides the consortium with completing the collaborative BOM cooperatively. In the cBOM-MS, BOM Navigator and cBOM Portal are positioned separately to reinforce the information security in the consortium during product development process.

1. INTRODUCTION

Nowadays, the global business environment tends to change to the direction that not only the customers’ diverse demands are swiftly reflected to the products to preoccupy the market but also their latent demands are predicted to create a new market. This environmental change strongly requires the innovation and change in the value chain of the product development as well as the product itself. But, as small and medium enterprises (SMEs) have no sufficient internal innovative capacity, they have to cope with this situation through the collaboration within the value chain of product development. That is, the small and medium manufacturers must endeavor to construct more diverse collaboration spaces in order to escape the simple OEM system and develop their own collaborative products.

In the product development procedure, diverse product-related data are generated and diverse transactions such as the collaboration with the associates are executed. Therefore, the systematic management is necessary in this space. Product data management (PDM) is a concept to obtain the total efficiency of engineering through the integrated management of all business process and information in the product life cycle. In general, a PDM system includes diverse functions to manage the product-related data such as project-related data, technical documents, drawings, and images and the related businesses process. Thus, it tends to be complex and expensive.

The collaboration among enterprises may occur in every product development process such as product planning, design, and manufacturing. In general, most SMEs in the value chains participate in the collaboration naturally. In the view point of individual enterprise, it participates only in a part of the collaborative project. Instead of introducing the expensive PDM system, thus it is desirable to use lighter and cheaper system which manages the basic information of the product clearly and efficiently. World-famous S/W companies have released diverse PDM systems with high functions, but it is still difficult for SMEs to purchase them in the aspect of use and expense due to this.

For the collaboration among SMEs in specific areas of the product development process, some web-based collaborative systems began to be developed in around 2000 to support the information sharing and communication among the subjects of planning/design/manufacturing who were geographically separated [1,2]. After then, the conference function which enables the data sharing and chatting via a viewer was developed [3,4], and diverse application technologies for the collaborative design were also proposed [5].

* Corresponding author: Tel.: (0082) 31-436-8054; Fax: (0082) 31-436-8050; E-mail:bhkim@kitech.re.kr
This study proposes the structure and functions of a design information management system centering on the BOM (bill of material) which can support the collaboration among SMEs in the product development process. The proposed system has expanded its functions to express the information of diverse configuration specifications on the basis of BOM function and the traditional basic information. In addition, it supports the collaborative environment, has enhanced the information security function, and was designed lightly to be fit for SMEs. Of the existing studies on BOM system, there are the Generative BOM processing system which supports the efficient management of BOM for a lot of end-item specifications [6-9], the Procedure-Oriented BOM system based on the structure of programming language [10], and the Variant BOM system using the coordinate concept [11].

2. USER REQUIREMENT OF COLLABORATIVE BOM

Before describing the user requirements of collaborative BOM (hereinafter, cBOM), let’s survey SmarTeam® and TeamCenter®, the commercial PDM systems based on CATIA® and UG® respectively, which are widely used in the automobile industry. SmarTeam® is the PDM system of IBM. It accumulates the data generated during the design, manufacturing, and maintenance stage and integrates the processes through the automated workflow and the management of revised items to provide the wide-ranged security, revision, document link, structure management, and decentralization environment for all product information [12]. On the other hand, TeamCenter®, the PDM system of Siemens, provides the efficient configuration management and variant management functions integrating total product structure, collaborative CAD assembly modeling, top-down design, and structural digital mock-up functions. Moreover, it shares the design model in the workflow-based process and supports the collaboration in the perfect digital environment [13]. Both of the systems are covering the whole period of the product and manage the product data through the workflow-based process integration. But the wide-ranged management function for all the products and documents is still too heavy and expensive for SMEs.

One of the most important functions of PDM is the management function of product structure and configuration. The product structure shows the relation of up-down assembly among the parts and has the information such as upper part, lower part, and necessary quantity. The product configuration shows the variant information such as the assembly specification and options. Only when this information is efficiently managed, the PDM can be used appropriately in the industrial site [14].

The cBOM management system (cBOM-MS) proposed in this study is to be designed lightly for the easy use by SMEs and to provide the product structure and configuration management function, the essential function of PDM. The cBOM system supports the product structure and configuration management on the basis of BOM. BOM is the central information of the product, and is used not only in the design but also in the manufacturing and the maintenance. Through the interview with design managers of SMEs, the requirements of cBOM-MS were found out as follows:

(1) Link of BOM-drawing-technical document: If BOM presents the relation among components and the characters of components, the drawing shows the concrete details of product and its components. The drawings express not only the image information but also the dimension information, the material information, and the processing information. The information not expressed on the drawing such as standards, environmental regulations, test conditions, and requirements of each country is described in the separate technical documents. For the easy and swift use in the project site, the basic information of BOM should be linked with the drawing information of each product and its components on the BOM list, and the related technical documents should also be checked together.

(2) Separation of internal-external collaboration for technical security: As the drawings and technical documents related with the product development are the essential asset of the company, the security management is very important during the internal and external collaborations of the company. Even if the collaboration is made, the existing processes

![Figure 1: BOM-centered link of CAD-technical documents](image-url)
and the product technologies of each company are the private asset of the company and should be protected. Meanwhile, as the added values generated in the collaborative space are the common asset of collaborative system which does not belong to one particular company, they should also be managed and protected in common. To satisfy these two contradicting requests, the BOM system used inside the company should be separated from the external collaborative system for the inter-company collaboration. Of course, the security management is possible even in the technically integrated system. But the personnel in charge of product development in the company strongly require the physical separation of the system.

(3) Provision of collaborative design function: Collaborative product development is neither the simple outsourced production nor the one-sided transmission of specification but the cooperative development with the joint development process. Thus, the cBOM-MS should provide designers of SMEs with the exchange of BOM as the basic design information, the delivery of drawings for the relevant product and the parts, the sharing of BOM structure and configuration meanings, and the management of revision during the collaboration of product design.

(4) Expansion of collaboration range: The collaboration range in the enterprise activities is indescribably diverse. The requirements and characters of collaboration space are all different according to the market size and the characteristics of the product. Thus, to be used easily by small and medium manufacturing enterprises, the proposed system should be executed easily and intuitively in the input of basic information and the definition of drawing number system for the flexible management of design information regardless of specific market or product group.

3. STRUCTURE AND FUNCTION OF cBOM SYSTEM

As mentioned in the previous chapter, the users strongly require the separation of internal and external collaborative business because of the security of technology. That is, as the essential technical information is stored and managed in BOM, it is natural to think of the security as important. In fact, the collaboration between companies is generally the vertical-type cooperation. Here, a leading company shares the minimum information for the collaboration and keeps the rest information secure strictly. In this study, the cBOM-MS is composed separately of the BOM navigator which can be operated inside the company and the BOM portal for the collaboration with other companies as shown in Figure 2. The BOM navigator provides the BOM interface function for the connection with general commercial CAD systems, and the BOM portal becomes the place to exchange the BOM among companies.

Figure 2: Structure of cBOM management system(cBOM-MS)
3.1. BOM NAVIGATOR

BOM navigator is the client/server-based BOM management system for the internal collaboration of the company, providing the information communication between design department and related department and the management of product data. In this study, the BOM managed by the BOM navigator inside the individual company is defined as the company BOM. Especially, as the company BOM generated by the leading company in the collaborative consortium has influenced on the total collaborative projects and is used as the standard, it is defined as the standard BOM. That is, the standard BOM is the basic BOM in the collaborative consortium, and the leading company and the cooperative companies should make the design cooperation to complete the reference BOM. The cBOM is the part (module/parts) separated from the standard BOM for the actual collaboration with the cooperative companies.

For example, let's suppose the situation that an automobile module is developed in the collaborative environment as shown in Figure 3. Here, the leading company is the manufacturer of the module, and at this time the module is consisted of two sub-modules as shown in Figure 3-(a). For the sub-module 1, the sub-module 1 composed of two parts is designed by the leading company itself as shown in Figure 3-(b). Meanwhile, the detailed designs of part 2-1 and part 2-2 of the sub-module 2 are carried out by the cooperative company 1 and 2 respectively as shown in Figure 3-(c) and (d). The part 2-1 has the specifications of ‘E’ and ‘F’, and the part 2-2 has that of ‘G’ and ‘H’. Here, the standard BOM is the BOM of the leading company, and the sub-module 2 including the part 2-1 and 2-2 defined for the collaboration of cooperative company 1 and 2 becomes the final cBOM as shown in Figure 3-(e). The final standard BOM is completed by combining the BOM of the sub-module 1 with the final cBOM as shown in Figure 3-(f).

![Figure 3: Completion procedure of the standard BOM through the collaboration](image)

The functions of the BOM navigator are largely classified into the regions of the company BOM management and the cBOM management. Each region consists of the main functions such as the management of BOM structure and configuration, the BOM edition, the auto numbering, the management of design revision, the management of history, and the link management of BOM-CAD-Technical documents. As shown in Figure 4, the company BOM has the
Design of Collaborative BOM Management System for Small and Medium Enterprises

hierarchy of components of a product or a module, and each component is composed of its registration information, history, related drawings, and related technical documents. In other words, the BOM tree presents the whole information of a product/module/part including the assembly structure of its components, its registration, history, related drawings and documents. From this reason, we can easily extract the hierarchy of drawings and technical documents independently from the BOM tree.

![BOM tree of a product/module/part](image)

Figure 4: BOM tree of a product/module/part

According to the various demands of customers, a product/module can be presented in several models, and even in one model which can be various variant products/modules according to the specification. Because of this, the information of products to manage grows in geometric progression, and the data overlapping problem can seriously occur in the aspect of data management. To solve these problems, this study proposes that the individual parts are maintained with the structure information and the variant information, and this information is expressed on BOM. In the traditional BOM systems, the basic view expressed in the form of tree is presented to manage the up-down relation between parts as well as the structure and the quantity. Meanwhile, the configurable view as shown in Figure 5 is provided to express the variant information in the proposed BOM management system. Furthermore, when the products, or modules, or parts are registered, the attributes of variant information are added/deleted, and the related information is presented in the relevant BOM according to the attributes and level of variant option.

The cBOM-MS for the external collaboration is the functions to generate and manage the cBOM by revising and editing the part of BOM of the leading company. That is, these functions are composed of the management of the registration information, history, related drawings, related documents, and input of the cooperative companies. For example, from the standard BOM of the target product/module some module/part to be designed collaboratively is separated to form the initial cBOM. Next, the information of relevant cooperative companies is inputted into the separated modules/parts and registered in the cBOM portal. In the cBOM portal, the registered cBOM is embodied through the collaboration with the cooperative companies. The embodied cBOM is verified and finally combined to the standard BOM.

3.2. COLLABORATIVE BOM PORTAL

In reality, the software module to execute the collaboration between companies is the cBOM portal. The cBOM portal exchanges the registered cBOMs with each other and manages the progression schedule of BOM, all the histories related with the cBOM, and the authority and the security of each company. The cBOM which is first registered on the cBOM portal, the initial cBOM, has not the detailed design of its components (modules/parts) but the specification of them. While the collaboration is progressed, the detailed design for each module/part is made, and the final cBOM is completed as the BOM tree of relevant module/part including the detailed design and related technical information. On the cBOM portal, each company can only register and read the cBOM. That is, unless the collaborative consortium allows the additional authority to it, the relevant company can only read the registered data and cannot delete or revise the data. Moreover, as all the records including the upload and download can be checked through the history management, it is clearly known when and who have used the system.

For example, in case of Figure 3, the leading company selects the sub-module 2 to execute the collaborative design using the BOM navigator and generates the initial cBOM from its BOM. In the initial cBOM, the sub-module 2 consists of part 2-1 and part 2-2. It has the specification information in which the part 2-1 and part 2-2 have the specification of E/F and G/H respectively and the information of cooperative company 1 and 2. Next, the leading company registers the initial cBOM on the cBOM portal to allow the cooperative company 1 and 2 to execute the detailed design. At this time, the initial cBOM is opened only to the cooperative company 1 and 2 to execute the collaborative design. If each cooperative company registers its BOM including the detailed design specification, drawings, and technical documents on the cBOM portal within the due-date, the final cBOM is completed. The leading company can read and use all the information of final cBOM including the opened information of the cooperative companies. However, the cooperative company can read not the information of other cooperative companies but the registered information of its own and the information opened by the leading company. After download of the final cBOMs to the BOM navigator, the leading company makes the final examination on them and completes the total standard BOM. This sequential BOM exchange process centering on the cBOM portal is explained in Figure 6 in detail.

![Figure 6: BOM exchange process](image-url)
### 3.3. BOM INTERFACE

Most companies create drawings using commercial CAD systems. In general, as the commercial 2D CAD systems usually express the product image in a planar way, the BOM should be separately generated. But recent 3D CAD systems can express the product information and the structure information of configuration parts in a tree form. Thus, for the better use of the proposed BOM navigator, it is necessary to provide the function to directly extract the BOM-related information created by the commercial 3D CAD system and to draw out the BOM automatically. In other words, the automatic BOM generation function is the interface function between BOM navigator and 3D CAD systems. This study developed this interface function and carried out its functional test in the CATIA® and UG® systems which are actively used in the automobile industry.

### 4. CONCLUSION

This study proposed the structure and the function of a BOM-centered design information management system which can be used for a SME consortium to carry out the collaborative development of new products. The proposed system has the structure and the function to manage the design data in connection with the part/drawing/technical document centering on the BOM which becomes the standard information of the product structure and configuration management. Especially, as the design information is an important asset of the company, the vulnerable security function in the collaborative environment was overcome by linking and separately operating the BOM navigator for the internal collaboration of the company and the cBOM portal for external collaboration among companies. In addition, as an interface to maximize the usability of proposed system, the automatic BOM generation function from the commercial 3D CAD system was proposed.

In the BOM navigator, the configuration management view was provided along with the basic view for the organic structure and specification management of products, modules, and parts and the variant information management. The company BOM of the leading company who leads the collaborative consortium is defined as the standard BOM, and the cBOM is drawn up by editing a part of standard BOM in the collaborative region and is open to the cooperative companies through the cBOM portal for the collaborative design among the companies. In the cBOM portal, the security by companies is managed so strictly that each cooperative company can read and revise only the information opened by the leading company and registered by the cooperative company itself. The proposed system is in the stage of prototype implementation as shown in Figure 7 and will be stabilized and complemented through the application to the design collaboration sites in the near future.

Active Disassembly application to enhance Design-for-Remanufacturing

Joseph D Chiodo and Winifred L Ijomah

1Active Disassembly Research Ltd.
London, UK

2DMEM
University of Strathclyde, Glasgow, UK

ABSTRACT

Developing sustainable approaches to remanufacture is a critical global concern because of manufacturing’s significant adverse environmental impacts. Remanufacturing is the process of returning a used product to at least original performance specification from the customers’ perspectives with at least “as new” product warranty. The practice is a more sustainable manufacturing mode because it is profitable but less harmful to the environment than conventional manufacturing. This paper discusses how ‘Active Disassembly’ (AD) could extend the application of remanufacturing in sustainable manufacture and proposes areas for further research. AD enables product non-destructive self-disassembly at end of life and was invented to facilitate a step-change improvement in recycling. However, the rapid disassembly with reduced component damage that it enables can increase remanufacturing economic viability. This is the first investigation into this specific link.

1. INTRODUCTION

Major global concerns include competition and environmental pressures, in particular waste from manufacturing. Significant factors of improvement must therefore be made in industrial practice and technological solutions [1] in order to attain a more sustainable mode of production and consumption. Product design must reflect this [2, 3]. Current product LCA demonstrates that the disposal phase contributes substantially to the environmental impact of Waste Electrical and Electronic Equipment (WEEE) [4, 5, 6]; particularly in products containing toxic materials [7], scarce or valuable materials, or materials with a high energy content. Within WEEE there is the combination of all three of these situations including for example, batteries, quality plastics, precious metals, and toxic solder. 1998 figures of E.U. WEEE was in the region of 6.5 to 7.5 million tonnes per year [8, 9], representing <1% of the total EU solid waste stream [10] and responsible for at least (base case scenario) 50% of metals in leachate, however, the quantity of electronic products and their waste is continuing to rapidly increase [11].

Remanufacturing, a process of returning a used product to at least original equipment manufacturer performance specification from the customers’ perspective with equal new product warranty [12, 13], is a central and profitable strategy in waste management, material recovery and environmentally conscious manufacturing. Remanufacturing’s significance is that it limits waste generation as well energy and resource consumption by manufacture. In contrast, conventional manufacturing generates in excess of 60% of annual non-hazardous waste [14]. Furthermore, increasingly severe legislation, such as landfill and end-of-life directives, demand reduction in the environmental impacts of products and manufacturing processes [15]. Since the Basel agreement [16] prohibits exporting of waste outside the EU, European producers must manage their waste internally. This, combined with rising fiscal penalties such as the landfill tax [17], and increasing global competition, makes remanufacturing expertise paramount. A key problem is designer lack of expertise in designing remanufacturable products [12, 18]. Currently remanufacturing is profitable typically for large complex mechanical and electromechanical products with highly stable product and process technology [12, 18]. Research indicates few examples where products with volatile product and process technologies are routinely remanufactured, chiefly as their remanufacture is cost prohibitive. ‘Active Disassembly’ (AD) is an alternative to conventional dismantling techniques that enables the non-destructive, self-disassembly of a wide variety of consumer electronics on the same generic dismantling line, thus reducing disassembly cost [19]. This paper illustrates the potential of applying this technology to WEEE remanufacturing. The importance here is that WEEE is the EU’s fastest growing waste stream [20], but small sized WEEE are typically not profitable to

* Corresponding author: Tel.: +44 (0)141 584-4346; E-mail: w.l.ijomah@strath.ac.uk
remanufacture as their volatile technological pace makes their disassembly by conventional means overly expensive. Remanufacturing aided by AD seems a natural progression of technology cross-fertilization.

2. Methodology

Remanufacturing related findings were obtained via literature search, telephone interview and observational case studies supported by interviews with key company personnel, informant examination of case study reports and experimental analysis. Results validation was by stakeholder review and peer review via publications. The stakeholder review involved testing for replication logic [21] by discussing the results with new remanufacturing practitioners at trade fairs and conferences as well as telephone discussion with new remanufacturers. For AD, as first conceived and implemented in 1990 by Chiodo, the technique has been applied to a variety of electronic products. Various applications and variations by other researchers and companies have contributed to this increasing body of knowledge [22, 23, 24, 25, 26, 27, 28]. Therefore, results of these findings were applied to design guidelines for remanufacturing such as those by Ijomah, [29]. Examples of candidate AD products include mobile phones, a variety of other small hand held electronics, home entertainment goods and automotive electronics (ECUs).

3. The remanufacturing domain

The key differentiating factors between repair, reconditioning, and remanufacturing include: (1) remanufactured products have warranties equal to new alternatives whilst repaired or reconditioned ones have inferior guarantees. Typically, with reconditioning the warranty applies to all major wearing parts whilst for repair it applies only to the repaired component. (2) Remanufacturing generally involves greater work content than the other two processes leading to products that generally have superior quality and performance (3) Remanufactured products lose their identity whilst repaired and reconditioned products retain theirs. Furthermore, remanufacturing requires assessment of all product components with those that cannot be brought back at least to original specification replaced with new (4) Remanufacture may involve upgrade of used products beyond the original specification which does not occur with repair and reconditioning. Reuse is the process of using functional components from retired assemblies [30]. Recycling is the series of activities for collecting, sorting and processing discarded materials for use within new products and is currently far more common than remanufacture [31]. Remanufacturing is preferable to recycling because it adds value to waste products by returning them to working order where as recycling simply reduces the used product to its raw material value [12].

![A generic remanufacturing process flowchart (Ijomah, [12])](image-url)
Remanufacturing begin with the arrival of a used product (a core) at the remanufacturer’s facility where they undergo a series of activities: disassembly, cleaning, component remanufacturing, replacement of unremanufacturable parts, reassembly and testing to produce the remanufactured product. All remanufacturing operations have this basic structure but the order in which these activities shown in Figure 1 and described in [32] are undertaken may differ between different product types [33]. Evidence of the environmental and economic benefits of remanufacture is well recorded in literature [12, 18, 34]. As consumers purchase remanufactured goods to obtain high quality products at low prices, remanufactured products must have high quality, reliability and low price, to compete against alternatives such as reconditioned and new products [12]. Much of the work to enhance products’ potential for remanufacture has been concerned with developing design-for-remanufacturing guidelines (DFRem) to assist designers because they lack remanufacturing knowledge. Examples of research in this area include [35, 36, 37, 38, 39, 40]. In addition to the above work that look specifically at remanufacture there are also other research that although not totally geared towards remanufacture none the less produce guidelines that can enhance remanufacturability, for example, [41, 42, 43, 44]. Although these research findings are commendable they do not address the issue of extending remanufacturing to product that experience high rates of technological change. The following sections will describe the AD concept and its potential to extend remanufacturing to fast moving consumer products.

4. ACTIVE DISASSEMBLY (AD) DOMAIN

AD, is a process by which an EoL product can non-destructively, self dismantle with the aide of embedded smart devices that are triggered by external energy input and are designed as part of the manufacturing and controlled hierarchical disassembly of the host product. In this study, three types of materials are employed within AD; the first two being either metallic or plastic. This process includes NiTi or Cu-based ‘Shape Memory Alloys’ (SMA) for AD-SMA, used for actuator devices. Polyurethane based ‘Shape Memory Polymers’ (SMP) are used for AD-SMP releasable fastener devices. Actuation of the SMA and SMP would occur just outside of world ambient temperatures for safety and practical reasons and would only change shape under the predetermined temperature. This ‘predetermined’ temperature is based on material composition and is therefore consistent and stable. This trigger temperature is referred to as ‘Tx’. The third ‘material’ is a conformal coating spray or ‘interstitial layer’ (IL); hence AD-IL. AD is particularly useful for complex assemblies typically with disassembly problems such as the requirement for very high product environmental performance (for example, extreme temperatures or vibration). Using SMA in the design of actuators, it is possible to effectively force the fastening elements of the products apart. This happens at the composition specific SMA Tx range; Austenite starting to finishing temperature (As-f). Below As the SMA actuator device lies dormant until exposed to it’s full Tx. SMA therefore possesses the ability to be stable in two different temperature states. When used in the design of a ‘smart material device’ (SMD), SMA is a force provider when triggered at this very narrow temperature bandwidth As-f, typically 14degC. SMA can be one-way [45], two-way [46] and less often, multi-way when used in the design of an actuator. SMP acts differently as it immediately looses shape integrity over a small temperature band with no accompanying force. It is therefore useful in the design of releasable fasteners capable of significant metamorphic shape change. SMP can be ‘called’ when triggered within a specific temperature exposure and range [47]. This is accompanied by a sharp drop in modulus. This engineering feature allows for an effective disassembly when the gripping portion of the SMP fastener looses its ability to hold its host together at its composition specific Glass Transition Temperature (Tg). When employed by AD, this would occur within its full temperature range completed at Tx. Just like SMA, the SMP SMD, lays dormant within its host assembly during the product’s use phase waiting to be triggered at EoL. Besides shape memory materials, there are numerous other ‘smart’ materials that can be employed to facilitate AD. These include engineering polymers, smart films, bio-degradable layers, adhesives, substances, liquids [48]. The technology offers a variety of dismantling applications. Numerous self-disassembling techniques have been investigated with varying levels of success, [22, 23, 24, 25, 26, 27]. It has been considered that these approaches can be categorized as automatic processes but labelled as ‘product embedded disassembly’ [28]. Different forms of AD also exist [49]. The following sections describe the application of AD to optimise WEEE recycling.

5. APPLICATION OF ACTIVE DISASSEMBLY TO WEEE RECYCLING

In conventional disassembly EoL products are dismantled manually, typically using pneumatic or hand tools. Manual disassembly has been used in recycling plants around the world to varying levels of success since the early 1990s. With high turn-over life cycle products like those in the technology sector, manual disassembly hinders profitable disassembly for telecommunication or other hand held electronic products. Significant economic

* Corresponding author: Tel.: +44 (0)141 584-4346; E-mail: w.l.ijomah@strath.ac.uk
efficiencies in disassembly is thus required to assure competitiveness in disassembly oriented EoL scenarios [28]. Invented to facilitate a step-change improvement in recycling, AD aims include hierarchical, controlled, non-destructive and specific product component release from macro to micro dismantling in order to optimise component re-use. The technology has been applied with great success in numerous items from automotive electronic control units (ECUs) through to laptops to home entertainment products, their sub-assemblies and most un-bonded components. Constituent assemblies here include housing, antenna, PCB, transformer, ECU and mechanical components. Figures 2, 3, 4 and 5 show the successful testing for non-destructive disassembly of a variety of WEEE products prepared with AD technology.

![Figure 2: Plastics dominated WEEE: AD-SMP embedded home entertainment (Chiodo et al. 2002 I Mech E)](image1)

![Figure 3: Precious metal dominated hand held WEEE: AD-SMA embedded (Chiodo et al. 2002 JM&D)](image2)

![Figure 4: Precious metal dominated WEEE: AD-SMP mobile (Chiodo 1998, ADR Ltd.)](image3)

![Figure 5: Metals/precious dominated automotive WEEE embedded with AD-IL (ADR. Ltd. 2002 and Arnaiz et al. 2002)](image4)

The tests here include hierarchical non-destructive disassembly which is particularly useful when the re-use required is of selected parts as opposed to all product components. These products, ranging from hand-held electronics to larger automotive electronics were modified with embedded AD-SMP, AD-SMA devices or an AD-IL. The figures illustrate various before and after samples. Figure 2, shows the pre AD of a Sony Playstation using an AD-SMP screw. SMA was used for actuator applications for AD in Figure 3. Precious metal content goods, as seen in Figures 4 and 5, illustrate potential use of AD with mobile phones and automotive goods also with high amounts of quality metal, aluminium in this case). Three different AD technology variants were tested and all examples were successful with non-destructive and low mean time dismantling. In addition, Chiodo has invented and experimented with numerous alternative approaches of AD technology to expand the potential repertoire of candidate products, for example, automotive ECUs as illustrated in Figure 5. This was employed because ECUs are almost impossible to economically disassemble cleanly. AD disassembly times ranged from one to 100s of seconds.
on products not redesigned for AD inclusion. Exact times for this study are irrelevant since any cost advantage in dismantling would only likely be realized in batch processing [19] as per any automated economically viable system. These new developments by Chiodo have illustrated the potential for more efficient and step change approaches to disassembly friendly product dematerialization design and manufacture strategies [48]. For the highest rate of automatic dismantling control: hierarchical, non-destructive, lowest mean time; would be achieved only if the products were designed with AD from the outset. Factors to be considered include a number of guidelines described in [50] and shown truncated in Table 1 below.

### 6. POTENTIAL FOR USE OF ACTIVE DISASSEMBLY TO ENHANCE WEEE REMANUFACTURING

Disassembly is typically an initial and critical activity in remanufacturing thus long disassembly time raises remanufacturing cost and lead times. Research, for example [12, 51]; have shown that the ability to disassemble is key for remanufacture because of its significant impact on the remanufacturing success factors of price, delivery and quality. In the case of price, customers are unlikely to purchase a remanufactured product unless it is less than ½ the price of the new alternative. However, high remanufacturing costs often result from resource consuming disassembly due to the time (and hence) labour costs and the need to replace components damaged during disassembly. Secondly, customers are unlikely to buy a poorly functioning product no matter how low its price. However, sound remanufacturing typically requires effective disassembly to ensure proper cleaning, assessment and rectification of internal components [12, 32]. Thirdly, unless the price of new products is prohibitive customers will purchase new alternatives rather than wait for lengthy time periods for a remanufactured version to be available. The above case studies clearly illustrate AD’s benefits in ensuring non-destructive disassembly coupled with reduced disassembly time and cost and hence it’s potential to enable profitable remanufacture of products that are currently not economically viable for remanufacture. Hand held WEEE including PDAs, calculators and mobile phones have been tested since 1996, originally for precious metal fraction reclamation [53], but there is also the potential for remanufacturing markets if enough through-put is achieved. Plastics dominated products such as home entertainment and brown goods also show promise, as illustrated in Figure 2. In assemblies where high performance sealants contaminate the potential for economic remanufacture, an automatic process is required to, through triggers including temperature (Tx), vibration and shear forces (tumbling), cleanly remove the sealant from the assembly as described in [48] and [54]. If products are designed for AD, time reduction and minimal (if any) evidence of dismantling would be achieved to increase the economic viability of their remanufacture.

### 6.1 BASIC FINANCIAL ANALYSIS

Figure 6, shows three categories of products of interest to implement AD within a pre-remanufacturing scenario; all but CRT products. For cost reduction to be viable, AD must be performed in large batch disassembly prior to remanufacture. Previous studies indicated that likely batch sized would be from 500 products to 1000 per 10 seconds [19]. Metal dominated products were not previously seen as viable, but the ECU presents a more positive scenario due to the high grade Al % content and a large PCB. Since the increase in automotive electronics is expected to continue AD presents the opportunity for 25% minimum cost reduction required for their market viable remanufactures. The following sections assess the potential for viable remanufacture of plastics dominated, common metals and precious metal dominated ELV WEEE products when AD-IL is applied. This process has an additional manufacture cost: the interstitial layer application: [48] ( http://www.activedisassembly.com/animations/il.html). However, it requires minimal design changes and provides clean separation from adhesives, silicon and other setting bonding agents that are typical in automotive ECU applications requiring high performance against the elements. When such products are redesigned with AD-IL inclusion, a batch of 100 to 1000 products could dismantle on average, every 10 seconds. Here, there is the potential to process five batches per minute in a large scale optimized
Remanufacturing is the process of returning a used product to at least its original performance from the customers’ perspective and giving it a warranty at least equal to that of a new product. It is an important re-use strategy in waste management, material recovery and eco-conscious manufacturing because it is environmentally and economically beneficial. AD is a process by which an EoL product can rapidly and non-destructively self dismantle with the aid of embedded smart devices to optimize component reuse. The major remanufacturing barriers include poor understanding of how to design products for remanufacture. Disassembly is typically an initial and critical activity in remanufacture. However, the research has shown that many products are not remanufactured because they cannot be non-destructively disassembled or their disassembly is expensive. This severely limits their potential for remanufacturing because remanufactured products must be at least 25% cheaper than new alternatives to win customers. Remanufacturers rejected jobs that were beyond economic repair (BER) unless there were strategic reasons, where BER was typically assessed as costing above 70% and 65% of new cost. Given the proven success in AD application to optimize component re-use in WEEE recycling, it seems natural to marry AD to design-for-remanufacturing. To this end, the rapid disassembly with reduced component damage that it enables results in increase in remanufacturing feasibility to extend the range of products that can be cost effectively remanufactured. Further research would include firstly, the application of AD to the design of selections of WEEE products to ascertain and quantify the impact on their remanufacturability and, secondly, the assessment of the viability of a market for the remanufactured, re-designed WEEE products.

The Fault-Ride-Through Capacity of Doubly-Fed Induction Generators (DFIGs) for Wind Applications

Wenping Cao*, Jessada Stevenson

School of Science and Technology
University of Teesside
Middlesbrough, England, TS1 3BA

Abstract

The behaviours of the grid connected Doubly-Fed Induction Generator (DFIG) responding to grid disturbances are studied in this paper. Grid disturbances include voltage sags resulting from symmetrical and unsymmetrical short-circuit faults. The analysis is carried out using real-time simulations on MATLAB’s SimPowerSystems models. Two types of faults including the single-phase and three-phase faults are simulated on a 3.96 MW wind farm connected to a solid 150 KV network feeder. A crowbar power electronic protection scheme is implemented in the circuit and used to aid the fault ride-through of the DFIG.

1. Introduction

Wind turbine utilisation is seen in rise in the electricity generation since the wind energy represents a promising source of renewable energy. As a result, numerous studies have been conducted to maximise the wind energy capture or to optimise the control strategies. However, the integration of wind energy into the power grid imposes certain impacts on the power grid, particularly the stability issue of the power system. On the other hand, the immunity of a wind farm to faults on remote and local buses from the power grid can also be of interest. The latter is often referred to as Fault-Ride-Through (FRT) capacity and is the focus of this paper. Figure 1 shows fault ride-through profiles for some European countries.

Despite early stagnation, wind power has grown very fast and has become commercially competitive with other means of electricity generation. At present wind turbines are being used extensively for large-scale deployment and play an increasingly significant role in the power network. Figure 2 illustrates the installed wind capacity for the year 2007. The UK, as the richest country in Europe in terms of wind energy potential, has installed only a small fraction of the world’s total wind turbines. This is partially due to the limited locations available for onshore wind power generation. Therefore, a significant growth area is expected to be offshore wind farms in the UK.
In the past, with low penetration of wind power into the grid, the power system was not affected by the presence of the wind farm. That is, the loss of power generation from a small wind farm did not pose a threat to the security of the overall power system. Nevertheless, since the size of wind farms is remarkably increasing, and so is the penetration of wind energy in the power network. Although the power system technology has been progressing dramatically during the past two decades with the help of improved power electronic devices, the reliability and security of the power systems still remain a significant issue. Thus, a better understanding of the impacts of large wind farms on the grid stability is required before any wind farms are interconnected to the grid. This involves the use of advanced wind farm dynamic models and analytical methods in solving potential problems of grid stability.

In this paper, methods of predicting and improving the low voltage ride-through capabilities of the wind farm are developed by modelling the dynamic performance of a power system. Power system faults, including balanced three-phase and single-phase-to-ground are investigated, based on dynamic and steady state analyses. In the dynamic simulation, the dynamics of a 3.96 MW wind farm connected to a 150 KV feeder whose data are extracted from the literature [3] is studied with relay protection and circuit-breaker settings included. Simulations are carried out using MATLAB’s simpowersystems with both phasor and detailed models employed.

Since the Doubly-Fed Induction Generator (DFIG) is currently the dominant topology for large wind power generation, its behaviours responding to grid faults are investigated in steady and transient states. A parallel grid side rectifier and series grid side converter are used to remedy a possible ride through fault whilst keeping the DFIG connected during grid faults.

2. OPERATION OF DFigs

For wind power generation, there are various types of electrical machines can be used in parallel with the wind turbine. An overview of the different wind turbine generator systems and their comparisons is given in [4]. The variable speed concept with a partially scaled power converter is known as the DFIG configuration. This technology allows extracting maximum energy from the wind for low wind speeds by optimising the turbine speed, while minimising mechanical stresses on the turbine during gusts of wind. As shown in Figure 3, this induction machine consists of a conventional stator which is directly connected to the grid, and a wound rotor which is connected to the grid via power electronic converters through slip rings. Clearly, the presence of slip rings leads to some disadvantages as they would require regular maintenance [5]. Also in Figure 3, the rotor power converters includes a rectifier (AC/DC) and an inverter (DC/AC), with a capacitor linked in between acting as the DC source. Forced commutated high switching devices such as insulated gate bipolar transistors (IGBTs) are usually employed in the power converter set-up so as to ensure accurate AC voltage from the DC bus link. The primary purpose of the two power converters is to control the rotor frequency and hence the rotor speed. The typical variable speed range for DFIG systems is about ± 30% of the synchronous speed. The rating of the power electronic converters is approximately 25-30% of the generator rated power, which makes this configuration attractive from an economic point of view. Furthermore, the DFIG configuration can also adopt the pitch angle control of the wind turbine blades so that the incoming wind power can be stabilised when the wind speed is too high.
3. GRID FAULTS

In order to fully appreciate the DFIG’s response to grid faults, an understanding of the different grid disturbances and their occurrences in any power system is of importance. In fact, power faults from the grid are many. However, open-circuit faults are not considered in this paper due to their relatively low levels of fault current contributions. Short circuit faults can also be divided into symmetrical and asymmetrical faults depending on if they are balanced among the three phases viewed by a fault. In three-phase power systems the short circuit faults are ranked in order of occurrence as follows: single line-ground, line-line, double line-ground and three phase faults. As a result, in this paper only single line to ground and three phase faults are modelled since they represent the most frequent and the most severe types in practice [6], respectively.

3.1. SYMMETRICAL FAULTS

The term symmetrical fault refers to power system faults where all three phases are effected equally. Symmetrical faults include phase-phase-phase and phase-phase-phase-ground faults.

Symmetrical faults can occur when insulation fails due to system overvoltages caused by lightning or switching surges, by insulation contamination (salt, spray or pollution), or by other mechanical causes as a result of adverse weather including falling trees on transmission lines. The resulting short circuit current is determined by internal voltages of synchronous machines and system impedances between the machine voltages and the fault. Fault currents can be many times larger in magnitude than normal operating currents. If allowed to persist they can cause adverse damage to equipment connected to the power system. As a consequence, it is usually necessary to remove faulted sections of a power network from service as quick as possible.

When a balanced three phase fault occurs in a balanced system there is only positive sequence fault current as the positive, negative and zero sequence networks are completely uncoupled.

3.2. ASYMMETRICAL FAULTS

Asymmetrical faults represent a short circuit in one or two phases of a three-phase system. Asymmetrical faults occur more often than symmetrical faults.

Possible causes of asymmetrical faults are:

(i) Line-to-line short circuit between any two of the three phases when lines come into physical contact as a result of a broken insulator.
(ii) Line-to-ground short circuit between any phase and ground, often caused by physical contact as a result of weathering (lightning, gale, forces, etc).

(iii) Double line-to-ground short circuit between two phases when they come into contact with the ground as well as each other, commonly due to adverse weather.

4. Simulation Models

The simulations for this experiment are carried out on the Matlab's SimPowerSystems. The experiment is based on a 3.96 MW wind farm connected to a solid 150 KV network feeder. Its phasor model is produced using SimPowerSystems generic DFIG blocks and also includes the power IGBT electronic converters Rsc and Gsc, as is illustrated in Figure 3.

A schematic of the wind farm for simulation is shown in Figure 4 and the parameter values for this wind farm are given in Table 1. The reactive power is initially set at 0 pu and when the voltage regulation mode is adopted the reference is 1 pu. The threshold for voltage regulation mode can be modified and action can be taken when the voltage at the generator terminals fall below this threshold, i.e. a turbine trip can be adopted. In order to comply with the U.K grid codes [7], the turbine must ride through the grid fault. As a consequence, the operation of the DFIG and its steady state performance are studied first, followed by analysing its transient response to grid faults. In this case, a parallel grid side rectifier and series grid side converter are also included in the models.

5. RESULTS AND DISCUSSIONS

The detailed model for simulation is shown in Figure 5. The phasor model was first run to simulate a three phase to ground fault on the 20 kV busbar of the plant and then a single-phase to ground fault. The faults were simulated for up to 3 seconds. Any power system fault lasting more than 3 seconds without being isolated by system protection is a very severe and unrealistic scenario. Although it is better to implement a long duration fault, a maximum of 3 second fault cycle is indeed sufficient for this purpose.

![Figure 5: Simpowersystems detailed model of the system (with crowbar protection circuit)](image)

5.1. Symmetrical Faults

Two models were produced with a phasor model which employs a generic DFIG block connected to a distribution network and a detailed model which represents the DFIG and detailed power IGBT electronic converters (Rsc and Gsc). In the phasor simulation method, the sinusoidal voltages and currents were replaced by phasor quantities at the system nominal frequency (50 Hz). Obviously the phasor model only takes into account the positive sequence currents and voltages while the detailed model however uses sinusoidal voltages and currents. The reactive power was initially set at 0 pu (also referred to as reactive power neutral) when the phasor DFIG block is operating in var regulation mode. When the voltage regulation mode is adopted the reference becomes 1 pu. The threshold for voltage regulation mode can be modified and action can be taken when the voltage at the generator terminals fall below this threshold, i.e. a turbine trip can be adopted.
Firstly, a 3 phase fault was simulated on the 20 kV bus bar. The phase-phase-phase fault was simulated for 1 second during steady state. No fault resistance is involved since the fault was not to connected to earth. The wind-farm can be operated in voltage regulation mode with the reference value at 1 pu or in reactive power regulation mode with the reference value at 0 pu. The simulation was ran with the pitch angle controller set to 2°/s and then to 10°/s for comparison of the performance in damping rotor over speed disturbances. These values were chosen as they are the fastest acting pitch angle used in practice [8].

Figure 6 shows the response of the DFIG wind farm to the fault on the 20 kV busbar with reactive power regulation mode.

![Stator voltage (pu)](image1)

![Stator current (pu)](image2)

![Generated active power at the stator terminal (MW)](image3)

![Generated reactive power (MVar)](image4)

**Figure 6: Simulation results for a 3 phase balanced fault on the system**

From the simulation results of Figure 6, it is evident that the positive sequence voltage falls below any of the fault ride through profiles so that the system is unable to ride through this fault simulated. As a result, a protection scheme is needed to aid fault ride-through for the system.

The stator voltage dips to almost 0 pu as the Rsc struggles to maintain the voltage to its desired set point of 1 pu. The lagging pitch angle controller over damps the rotor speed after fault clearance which causes a reduction in generated power after fault clearance of 30s. The rotors over currents are significant rising the DC link voltage to 4 times its nominal value. However, the faster pitch angle controller is able to damp the over speed quickly and the effects of over damping are thus not significant. The effects of the over damping can be seen on both simulations results for 2°/s and 10°/s pitch angle controllers.

The DC bus link capacitor rises to a peak value of 5.25 kV, which is twice the rated value. This suggests high levels of surplus rotor current from the symmetrical fault simulations. Even at the fault instant the DC link voltage rises to approximately 2.5 kV, which is still above the capacitors capability.

### 5.2. Asymmetrical Faults

The phasor model was run to simulate a single phase to ground fault on the 20 kV busbar of the plant with the fault simulated for 3 seconds. Test results in var regulation mode are shown in Figure 7.

From these results, it can be seen that the variations in stator voltage and current, in active and reactive powers are all less significant compared to the three-phase fault, in particular the stator voltage and active power. Due to the nature of induction machine which draws reactive power from the grid, reactive power compensation is always required for DFIG applications so as to enhance the machine’s ride-through capacity. When the remedial method is applied, these variations are all reduced but the generators can ride through the faults defined in the grid codes.
In addition to the stator voltage, the rotor current is also a concern when evaluating the DFIG’s fault ride-through capability. The transient rotor current is largely dependent upon the power converter characteristics whose rating is only a fraction of the generator rating. When a disturbance occurs, there is a sudden step changes in AC stator voltage throughout the disturbance owing to the magnetic coupling between the rotor and stator.

However, the power electronic converter is limited to only 30% of the generator power rating. When the change in stator voltage is large, the rotor circuit can not follow the change in stator voltage. Unfortunately the power electronics make up a large proportion of the wind turbine capita therefore increasing the size of the power electronic rating is not a feasible option from an economic point of view and the rotor side converter must be protected from the high current transients. As seen in the simulation results, the rotor current transients raise the DC voltage. The generic DFIG model does not provide more detailed rotor current analysis but analysis of the DC bus link is proved to be sufficient in this respect.

5.3. Fault Ride-Through Protection

The power electronic converters require protection from the transient rotor currents that raise the DC bus link voltage of the power electronic converters. From foregoing analyses, during single phase-ground faults the DFIG can ride through the fault without additional protection, although the oscillations in DC bus link voltage may be of particular concern as the oscillations that occur on the rotor shaft may cause mechanical stress. During 3 phase-ground faults, protection of the DC bus link capacitor and IGBT’s are inevitable since the rise in the DC voltage is more significant. For this purpose a control scheme can be adopted to achieve this after analysing the behaviours of the detailed model of the wind farm during faults which were illustrated previously and which took the voltage at the limit of the fault ride through profiles.

As mentioned previously, the 3 phase symmetrical fault represents the most severe type of faults. In this paper, therefore, only 3 phase symmetrical fault on the 20 kV bus bar is investigated with power electronic protection scheme implemented. The scheme adopted is known as a crow-bar circuit [9]. In essence, a crowbar circuit is operated by adding a short circuit or low resistance path across the voltage source and is implemented by disconnecting the rotor side converter and short circuiting the rotor windings. The rotor side converter can be disconnected via a 3 phase contactor in the simulation model and the rotor windings can also be short circuited via a trip circuit. Simulation results with the protection circuit are shown in Figure 8 for comparison of that without such a scheme as shown in Figure 5.
With the fault ride through technique implemented, the DC bus link voltages is protected from the rotor over currents that rise the DC bus voltage during 3 phase to ground faults. Therefore damages to the IGBT’s is avoided. However, when the rotor-side converter is re-engaged after fault clearance, there is still a slight rise in DC bus voltage which may potentially rise the voltage to that without the protection scheme.

6. SUMMARY

A study of the DFIG’s behaviours responding to grid disturbances has been described in this paper. Grid disturbances studied include voltage sags from symmetrical and unsymmetrical faults. Simulations results confirm the DFIG can ride through the faults defined in the UK grid codes with the help of a crowbar protection circuit.

Predictive Simulation for Model Based Energy Consumption Optimisation in Manufacturing System and Machine Control

Anton Dietmair*, Alexander Verl, and Philipp Eberspaecher
Institute for Control Engineering of Machine Tools and Manufacturing Units (ISW)
Universität Stuttgart
70174 Stuttgart, Germany

ABSTRACT

Resource efficiency and most of all energy efficiency have recently come to the focus of attention of production engineers, especially from the perspective of lean methods. As a prerequisite for optimisation, we show how the energy consumption of various production machines can be accurately predicted and how single machine energy consumption models can be integrated into models of more complex manufacturing systems with multiple machines and multiple types of energy carriers like electricity, pressured air and coolant. We go on to introduce model based energy consumption optimisation strategies that take into account goals in time, quality and cost and provide for an absolute reduction of the amount of energy consumed as well as peak power flattening. To maximise the operational flexibility while optimising the energy consumption, we focus not on permanent measures, but on methods that optimise the controllable machine and plant parameters in a situation-oriented manner. We conclude our paper with guidelines on how the techniques can be applied in industry.

1. INTRODUCTION

Resource efficiency and most of all energy efficiency have recently come to the focus of attention of production engineers and enterprises worldwide. Partly, this is due to the legislative pressure to raise energy efficiency [1]. But at the same time, innovative providers of high quality manufacturing solutions, see economic and ecologic sustainability no longer as antagonistic goals but as an opportunity to compete based on total life cycle cost instead of investment cost [2]. At the same time, lean principles have always been a core tool to achieve efficiency in manufacturing and beyond by identifying and eliminating waste [3]. To reach its full potential for continuous optimisation of production processes, lean production today relies on prediction and simulation based techniques [4]. For the particular case of sustainability in manufacturing, the energy consumption of manufacturing machines and systems has to be predicted and methods have to be provided to minimise the amount of energy consumed.

Therefore, based on the energy consumption model we presented during the FAIM2008 conference [5], in this paper we demonstrate how the energy consumption of production machines can be accurately predicted and how these models can be integrated into models of more complex manufacturing systems with multiple machines and multiple types of energy carriers like electricity, pressured air and coolant. Predictive simulation together with sensitivity analysis provides the basis for the accurate prediction of manufacturing system energy consumption that is required for energy procurement. We go on to introduce model based energy consumption optimisation strategies that take into account other goals like processing time, workpiece quality and machine and tool wear and provide for a reduction of the amount of energy consumed as well as peak power flattening. To maximise the operational flexibility while optimising the energy consumption, we focus not on permanent measures, but on methods that optimise the controllable machine and plant parameters in a situation-oriented manner. We conclude our paper with guidelines on how the techniques can be applied, either by manufacturing enterprises or by energy efficiency service providers.

2. ENERGY CONSUMPTION MODELLING AND PREDICTION

2.1. ACCURATE MACHINE TOOL ELECTRICAL POWER CONSUMPTION MODEL

The electrical power consumption of a production machine is given as the sum of the consumption of individual components of the machine. This, in turn, is determined by the operational state, which defines which components are active and thus consuming a certain amount of basic power, as well as the movements and manufacturing process executed by the machine. Figure 1 shows the corresponding elements of an energy consumption model and the interdependencies present between these elements.

As has been shown in [5], the basic consumption per operational state contributes a substantial proportion to the total energy consumed by a typical production machine. It can be modelled based on a state-transition graph and activity flags or power intake levels per component and state (Figure 2). This is typical for production machines today, which often have a large offset power intake independent of the manufacturing process [6]. Such a discrete event model without any extensions can already be used to optimise the operation of machines and production plants and to determine the relevance of the individual components for the total energy consumption [7]. An important aspect of the discrete event modelling consists of including the relevant time behaviour, e.g. the minimum time span a machine stays in a run-up state before being able to enter the next state, or stochastic mean times before transition.

Moving parts of the machine and the work piece contributes a second major component of the total energy consumption of a production machine. The motions and inertia forces themselves can normally be approximated using only kinematic modelling. In cases of highly elastic components, using simplified dynamical modelling is appropriate. Modelling and predicting the motion induced power consumption is of special interest for quantifying the energy savings that can be realised through energy recovery systems that feed back power into the grid during deceleration as well as light weight engineering methods that seek to minimise the amount of moving mass [8].

Figure 1: The electrical power consumption of a machine depends on its operational state, motions and processes.

Figure 2: Basic electrical power consumption per operational state and component for a milling machine.
Equation 1 can be used to compute the instantaneous electrical power consumption based on moving mass, acceleration, velocity and friction, and Figure 3 shows the good correspondence for the example of a milling machine:

$$P_{el,\text{motion}}(a, v) = \eta_{el} \left[ P_{\text{mech,acc}}(a, v) + P_{\text{mech,fric}}(v) \right] = \eta_{el} \left( m \cdot a \cdot v + F_{\text{fric}} \cdot \max\left(\left| v \right| \cdot \left| \text{sgn}(v) \cdot v_{\min} \right| \right) \right)$$  \hspace{1cm} (1)

where $P_{el,\text{motion}}$ = electrical power consumption due to motion, $a$ = acceleration, $v$ = velocity, $\eta_{el}$ = degree of efficiency of the motor and drive, $P_{\text{mech,acc}}$ = mechanical power required for acceleration, $P_{\text{mech,fric}}$ = mechanical power required to overcome friction, $m$ = accelerated mass, $F_{\text{fric}}$ = friction force and $v_{\min}$ = low speed model boundary.

While all shares of the total power intake introduced so far are independent of the benefit of the operation of a machine, the energy for the manufacturing processes not only contributes to the total energy consumption, but also quantifies the benefit of the machine. The nature of the manufacturing process and the equations for the computation of the processing power depends on the machine and its application. While in the case of a handling device the power equations will be similar to Equation 1, specialised equations can be given for processes modifying the workpiece by forming, cutting, grinding or milling, and even non-conventional tools like lasers can be modelled in their energy consumption [9]. A few publications on the influence of process parameters on the total energy efficiency of the manufacturing system exist [10]. In cases where no special results on the energy efficiency of a manufacturing process has been published, sufficiently accurate predictions about the power consumption can often be made based on equations for process planning and coefficients from standard handbooks, e.g. [11], as the example for the cutting power of a milling machine in Figure 4 and Equation 2 illustrates:

$$P_{el,\text{milling}} \left( d_{\text{cut}}, v_f \right) = \eta_{el} \cdot P_{\text{mech,milling}} \left( d_{\text{cut}}, v_f \right) = \eta_{el} \cdot d_{\text{cut}} \cdot v_f \cdot \frac{z_e \cdot k_c \cdot D}{z_w \cdot (\phi/360^\circ)}$$  \hspace{1cm} (2)

where $P_{el,\text{milling}}$ = electrical power consumption due to milling, $d_{\text{cut}}$ = depth of cut, $v_f$ = feed rate, $\eta_{el}$ = degree of efficiency of the motor and drive, $P_{\text{mech,milling}}$ = mechanical power required for the milling process, $z_e$ = number of cutting edges active in parallel, $z_w$ = number of cutting edges in total, $k_c$ = specific cutting force, $D$ = tool diameter and $\phi$ = cutting zone angle.

A number of other, more specific contributions to the overall energy consumption of production machines exist. One example are supply units that receive their electrical power through the machine and provide services like lubrication, but are not constantly running or linked to the operational states of the machine itself. In some cases, the temporal behaviour can be modelled based on the service provided and the usage of the machine. In most cases, though, their contribution is small compared to the basic consumption, motion and processing power.
2.2. Including Different Energy Carriers in the Model

A common mistake in energy consumption assessment of manufacturing systems is to limit the evaluation on the electrical power intake of an individual machine and to ignore non-electrical flows across the chosen system boundary as well as services that are necessary for the operation of the machine. It is also typical to study the degree of efficiency of supply units and to select particular solutions based on only the maximum possible requirements, while many supply units are actually operating at inefficient partial load conditions most of the time [12].

Typical non-electrical supply demands of production machines include pressured air, hydraulic oil pressure, lubrication, high and low pressure coolant and process heat. Some of these are put into the manufacturing system context for an example situation in Figure 5. It can be seen that some demands are covered by local supply units installed in or near the machines (typically hydraulics and lubrication, Supply Unit 1 and 4), while others are met by centralised units and factory-wide transport networks (e.g. pressured air, Supply Unit 5).
Central supply systems are often combined with local units for final conditioning of the supplied media. For example, this is typically the case for coolant, which is prepared centrally and fed to a large number of machines through a supply network. It is then pressurized by a local pump and fed into a single machine or a group of machines (Supply Units 2 and 3). After the used coolant leaves the machine, special devices separate chips from the fluid and feed the coolant back through a network into a recycling system. All mentioned steps require energy, and other forms of disposal and waste removal, e.g. vacuum devices for dust removal or structural cooling fluid networks, follow the same basic principles. In the case of structural or electrical cabinet cooling, it depends on whether the waste heat can be used as process heat or heating for buildings whether the heat is regarded as a loss. Services like workpiece handling, tool renewal and maintenance are required for machines to fulfil their tasks, so the energy consumed creating these services has to be taken included in the overall energy balance of the production. From what has been said it is obvious that judging the overall energy efficiency of a production system requires taking its nature as a network into account and quantify energy flows represented by different media and services.

Based on the structure of the power consumption model in Figure 1, this is easily possible. There, the total power intake consists of the individual power demands of the active components. These components can be either local, like electrical motors and drives moving the axes of a machine, or central supply units shared by machines over a network. In the former case, their electrical power consumption goes directly into the mains power intake of the machine itself, while in the latter case a proportion of the power consumed by the supply unit can be assigned to the machine indirectly via calculation of the supply demand of all connected machines. The role of component models in the energy consumption model is the transformation of a quantified demand of e.g. coolant with specific properties, e.g. pressure, and calculate the electrical energy required by the component to meet the demand. Internally, the structure of a supply unit model is similar to that of a machine and thus follows Figure 1 with manufacturing process modules replaced by demand fulfilment modules. Some supply units show a constant electrical power consumption for an operational state, while the power intake of others will depend on the flow of media drawn by the machines.

In most cases today, the control of supply units is strictly local and based only on the observed flow of media, pressure drops and the like, but the energy efficiency of supply networks can be raised if the demand is predicted and communicated by the machines. While fully centralised supervisory control for media scheduling contradicts the lean principles and would lead to reduced reliability, local communication of demands and robust supply control strategies are lean compliant and can contribute to waste elimination. This is illustrated by dashed lines in Figure 5.

2.3. COMPOSITE MODELS OF MACHINES AND MANUFACTURING SYSTEMS

In the previous paragraph, it has been shown that the energy consumption behaviour of a machine is determined not only by the machine itself, but also by the supply units. At the same time, the operation possibilities of a machine at any time are restricted by the behaviour and operational states of the supply units. Using the product graph of the individual operational state machines as a model for the overall behaviour is limited to systems with very few subsystems that each have only a very small number of states, as the number of states of the product graph will be very large otherwise. Using the graphical formalism that is well established for Petri Nets, with circles representing states, bars representing transitions and markers denoting the active states, Figure 6 illustrates possible approaches to building composite models from multiple subsystems. Following the direction defined by the graph, a transition is unlocked when all preceding states carry markers. As soon as the transition is activated by an external event, the markers from the preceding states are removed and new markers are added to the subsequent states. We apply this to link elementary models which each have one active state of their own, but share synchronous transitions [5].

![Figure 6: Composite models of functionally linked components (dashed) created with linked (a) or independent states (b).](image-url)
Figure 6a shows a simple example for a machine and its coolant supply unit linked by the transitions representing the events “switch coolant on” and “coolant switched off”. Both the machine and the supply unit now can have an energy consumption profile attached to their operating states, with the total power intake resulting as the sum of both. In addition to that, each operational state may have a more complex parameter dependent behaviour. For example, the energy consumption of the coolant supply unit may be dependent on the flow rate of coolant drawn by the machine (dashed line in Figure 6a). Sub-models may also be linked by functional dependencies, even if there are no control mechanisms linking their operational states. Figure 6b shows this for the example of a milling machine that receives its coolant from an independently acting supply unit, with the presence or absence of the coolant flow clearly determining the possible manufacturing processes and process parameters.

It has to be stated that interdependencies in manufacturing systems are not limited to the supply network, but are often also given by the workflow and by machines, handling units and other components interacting. These structures can also be modelled as a composite of a number of elementary operational state graphs. Figure 7 illustrates this for the example of a milling machine fed by a handling robot from two conveyor belts. Each operational state is assigned an energy consumption profile like the one introduced in Figure 2 and the total instantaneous power intake is given by the sum of the individual power consumption associated with all states carrying a marker. In most cases, synchronous transitions are sufficient to link the elementary models, like for the conveyor belts and handling robot in the example. More complex interactions, e.g. between the handling robot and the milling machine, can be defined using additional states. In the example given, this allows the robot to load a workpiece into the machine even if the machine is not yet ready to start milling. Additional states typically do not add to the total energy consumption.

3. SIMULATION BASED MULTI-OBJECTIVE ENERGY CONSUMPTION OPTIMISATION

Avoiding and eliminating waste is a core principle of lean production. Over-engineering and centralised control with the aim to raise efficiency would not only contradict the lean principles, but often lead to diminished production system reliability and productivity. Robust decentralised control solutions complemented by global system modelling and simulative optimization, in contrast, are viable strategies to detect inefficiencies and avoid waste. Together with [5], chapter two of this paper provides the framework for modelling the energy consumption behaviour of machines and manufacturing systems in a way that allows to optimise the usage profiles and control strategies. Optimisation must not only take into account the total energy consumption and peak power relevant for energy procurement and saving a large proportion of the total lifecycle cost of production systems [13], but also other objectives like machining time, workpiece quality, tool and machine wear, and other elements of the life cycle cost like investment. Some of these objectives are straightforward to assess in the context of the energy consumption modelling approach presented here, e.g. machining time and investment cost, while others like workpiece quality and wear require models of their own. Models in these areas are increasingly available, and depending on the manufacturing task, the information available about the production system and the goals, a tailored optimisation strategy can be chosen. While [5] named a number of possibilities for simulation model based energy efficiency optimisation in planning, in this section we will give examples on how model based automation can be used to raise energy efficiency.
3.1. SELECTING OPTIMAL MACHINE PARAMETERS

The first possible way to optimise the usage of machines is to determine machine and process parameters that satisfy the criteria in an optimal way. A typical machine parameters that can be subjected to optimization is the maximum acceleration for interpolation of numeric control programmes. Reducing the maximum acceleration leads to substantially lower peak power and reduced machine wear, while the machining time increases. The longer machining time means that the basic power of constantly running machine components and supply units is consumed over a longer time, eventually leading to higher total energy consumption per manufactured part. A process parameter that can be used to influence the amount of energy required per manufactured part is the feedrate. While a high feedrate leads to a short machining time and thus to a reduced duration of basic power consumption, going beyond a limit specific to the process, both the instantaneous efficiency and the quality of the machined surfaces is substantially diminished. Finding the strictly optimal parameter settings requires a very deep understanding of the manufacturing process and is not always practical [10], but a basic energy consumption model can contribute to improvement.

3.2. LOGIC AND SEQUENTIAL CONTROL PROGRAM OPTIMISATION

A second and more substantial possibility for energy consumption reduction lies in the programming of the logic and sequential control of production machines and systems. This can be illustrated by the example of an automatic hibernation mode of a production machine given in Figure 8. There, it is known at a specific point of time that the machine will be idle for a known time span. Two possibilities for energy saving action exist, namely to switch off the machine and then re-start it again (Figure 8a) or to switch off only one component that can be re-started instantaneously (Figure 8b). Switching off the machine in this example actually would increase the total energy consumption, as the time the machine is consuming no energy is short and a number of operational states with high power consumption have to be entered during the re-start. In addition to that, the machine would be available only after the scheduled time. Consequentially, an automatic control algorithm based on the energy consumption model would choose option b. More concepts for optimisation techniques that can be implemented in programmable logic control are given in [14]. In addition to machine controls, the sequential control of a manufacturing system including scheduling can be optimised using model based total energy consumption prediction as well [15]. During any automatic optimisation, aspects like usability and thermal stability have to be taken into account.

3.3. OPTIMISATION OF NUMERICAL CONTROL PROGRAMS

In the stage preceding execution of machining programs on machines and manufacturing systems with or without energy optimal logic and sequential control, Computer Aided Process Planning and Manufacturing (CAP/CAM) tools can be used to find the optimal strategy producing parts on a manufacturing system. As illustrated by Figure 9, Numerical Control (NC) simulation can be combined with the model presented in this paper to determine the energy consumption for any machining strategy and process alternative, e.g. dry machining. Optimization algorithms and software can then be used to find the variant with minimal energy consumption that satisfies all other constraints.

3.4. GUIDELINES FOR MODEL BASED ENERGY OPTIMISATION

The examples given above highlight the high potential that is hidden in model based optimization and automation to achieve substantial improvements in energy efficiency of machines and manufacturing systems in a lean way. The central question that has to be addressed is how machines and manufacturing plants can be operated with high efficiency under partial load conditions, as partial load conditions take up most of their active time [14].
Selecting the optimal level of detail for practical model-based optimization can be achieved by following lean principles in applying the framework introduced here. Different approaches can then be followed to optimize the usage and control of manufacturing systems. These include sensitivity analysis to determine the parameters that have a big influence on energy consumption and other goals, pareto analysis, search heuristics and evolution strategies to find the attainable global optima and breaking down the problem into robust operational state-wise optimization.

4. SUMMARY

In this paper, we have introduced the framework for accurate modelling of production system energy consumption, with special emphasis on the dynamic elements of manufacturing machine power and the inclusion of non-electrical energy. We have gone on to demonstrate how composite models can be built out of simple elementary energy consumption models of individual machines and components. Based on examples for the simulative optimization of controllable parameters, we have given guidelines for model-based energy consumption optimization.

Bionics – An Inspiration for Intelligent Manufacturing and Engineering

Bill Gaughran and Sonya Quinn

Department of Manufacturing & Engineering
University of Limerick
Ireland

ABSTRACT

Value creation in all its facets lies at the core of intelligent manufacturing and engineering. In the last twenty years the field of manufacturing has undergone many changes and refinements. Terms such as Integrated Management Systems (IMS), Just in Time (JIT), Toyota Production System (TPS) in the context of Lean Production and ‘Flow’ were parts of the toolset developed by the Toyota Corporation which pushed them to the forefront of world automotive production. While benchmarking the design production systems and their associated efficiencies is very worthwhile, there are other engineering design, lean production, just in time, and production and supply chain exemplars which are worth investigating. A primary source of best-practice engineering in flexible and intelligent manufacturing is to be found in the study of ‘Bionics’ (Biomimicry). The intelligence in design and operational efficiency which is brought to Bionics by design in nature was recognised by Leonardo DaVinci when he wrote: “…in her (design) nothing is lacking and nothing is superfluous” [1]…This paper examines how design and engineering can learn and apply through the study of bionics/biomimicry, a vast pool of knowledge of design and systems engineering strategies. Such strategies and exemplars will provide benchmarks which will result in inspirational approaches in design, efficiency and sustainable engineering solutions.

Keywords: Efficiency, Sustainability, Energy Management, JIT, Lean, Bionics.

1. INTRODUCTION

Long before contemporary terms such as bionics, biomimicry, biomimetics, biognosis or bionical creativity engineering became well-know, people have appreciated the beauty and design in all aspects of nature. What is Bionics or Biomimicry? (From bios – life, and mimesis – to imitate). It may be described as an innovative approach to design and engineering, inspired by design in nature. The wise King Solomon of ancient Israel stated more than three thousand years ago that: “…there is nothing new under the sun” (Eccl. 1:9). It might be claimed that this ancient had little to compare with, and the wonders of modern technology were long in the future. However, today and into the future engineers and designers will do well to pay strict attention to specific detail and systems design in nature so as to draw inspiration for efficient, renewable, self sustaining, and ultimate solutions to problems of environmental sustainability. ‘Innovation inspired by nature’ [2], can lead to a new path of discovery and problem solutions, which for the most part have been overlooked. Nature is the ultimate exemplar in ‘eco-design’, and deserves the full attention of all who endeavour to tackle the problems of sustainable technologies in energy, materials, medical engineering and technological innovation. Why? Well when we examine closely its designs and systems we see that nature:

- runs on sunlight;
- uses only the energy it needs;
- fits form to function
- recycles everything
- rewards cooperation
- banks on diversity
- demands local expertise
- curbs excesses from within
- taps the power of limits

A design specification such as the above would frighten any team of experts, and yet this is what we find in nature. When people appeared to lead more leisurely lives, they seemed to appreciate these facts more
than we do today. Even in rudimentary ways DaVinci (1452-1519) tried to mimic flight (see Figure 1). It didn’t fly, but he was thinking in the right direction.

One of the good things about modern technology is that it does provide greater opportunity to mimic natural design and to test its effectiveness. Towards that end this paper will look at natural and applied examples from the skies (birds) the seas (fish/mammals) and the land. All of these, make up the entire eco system, but each has its own ecosystem and in turn sub-systems.

Another ancient character who recognised this was the man Job, known for his patience, Moses wrote in the book of Job, nearly five hundred years before King Solomon:

“Ask please the domestic animals and they will instruct you; also the winged creatures of the heavens, and they will tell you. Or show your concern for the earth and it will instruct you; and the fishes of the sea will declare it to you.” Job 12:7-8.

In examining some of the examples in nature that Job observed, and in the context of available, and yet to be developed contemporary technologies, it can be seen how these may be harnessed to inspire new approaches to design and engineering. Approaches, which in the context of mimicking design in nature, have the potential to fulfil some or all the criteria listed in paragraph one above, and so provide engineering solutions which are energy and environmentally sustainable.

2. THE WINGED CREATURES AND THE FISHES

While DaVinci’s ‘flying machine’ never got to fly, birds/mammals such as the seagull and the bat have been the inspiration for advancing efficient technologies. Funded by the U.S. Air Force and NASA, US aerospace engineers have built prototypes of 150 mm to 600 mm drones capable of squeezing in and out of tight spots in cities — like tiny urban stunt planes. Their secret: seagull-inspired wings that “morph,” or change shape, dramatically during flight, transforming the planes’ stability and agility at the touch of a button on the operator’s remote control [3].

Currently at the University of Limerick the ‘cranked’ wing is being tested on large model (1800 mm) aircraft, to determine the manoeuvrability and fuel consumption. Additionally the model is being tested with and without leading edge wing-‘tubercles’, this idea is inspired by the very large but highly manoeuvrable Humpback whale. Wind tunnel tests of model humpback flippers with and without leading-edge tubercles have demonstrated the fluid dynamic improvements tubercles make, such as a staggering 32% reduction in drag, 8% improvement in lift, and a 40% increase in angle of attack over smooth flippers before stalling. A company called WhalePower is applying these lessons to the design of
wind turbines and fans of all sorts – industrial ceiling fans and other HVAC systems, computer fans, etc. – to improve their efficiency, safety, and cost-effectiveness [4] In Australia the use of fan blades with ‘tubercles’ used in air conditioning systems, save significantly on energy and run much quieter. These giant creatures of the seas may weigh thirty-six tones, and measure up to fifteen meters in length. Figure 3 below shows an illustration of the ‘bubble net’ of the whale (d), close-up of his flipper (a) and a line diagram of the hydrodynamic flow pattern comparisons between a smooth leading edge and a tubercled one (b). Also shown is a close up of a wind turbine blade (c) for electricity generation with a similar leading edge. In addition to increased efficiency, the latter also contributes to overcoming the general objection of noise pollution from conventional turbine blades.

The airplane experiment described above will attempt to reduce drag and so save fuel and thus CO2 output. The combination of the cranked and tubercled wing, appear to have good potential, the tests are ongoing. If the hypotheses are correct there are likely to be highly significant gains in aircraft technology and efficiency.

We have also much to learn from birds and sea creatures about how to use and transfer energy. Returning to the seagull the question arises: why this and other birds who may be constantly standing on ice do not freeze, or why some fish in extremely cold seas continue to function well. The answer lies in their built in counter-current heat exchange design. The veins and arteries pass in contact or may be linked by shunts, where the warmer blood in the arteries heats the cold in the veins. For example by the time the cooler blood reenters the body of the gull from the ‘cold feet’, it is only two degrees Celsius cooler. Figure 4 shows diagrammatically the heat exchange mechanisms in gulls and fish.

The applications of heat exchange are numerous and highly beneficial in the efficient running of low energy heating systems. When, for example, a geo-thermal or air-thermal heating system is installed, and the heat pump unit has elevated the ground temperature from 12° Celsius to 22° degrees Celsius, it would be extremely wasteful if the exhaust air or fluid were simply returned to source without having a system of elevating the temperature of the incoming replacement. This is accomplished by the seagulls legs counter-flow heat exchange principle.

This is just another example of the benefits of looking at design in nature through the observant eyes of men such as Job or Leonardo DaVinci.
The applications resulting from such understanding, are used in many heating systems - shown in Figure 5 below are diagrams of a geothermal energy system for a home and the heat exchange unit which adds to efficiency by significantly reducing lost energy.

Mammals, both sea and airborne offer an infinite source of inspiration to engineers and designers. This is already being applied in sonar and radar systems which keep us safe while ‘flying’ or assist trawlers to locate fish etc. Hikers moving through unfamiliar territory are well advised to carry a compass, if not a GPS unit, to stay on course. Other animals appear to have complex navigational equipment in-built. New research reveals that Israel's blind mole rat (Spalax ehrenbergi) uses the Earth's magnetic field on long journeys, much like a compass, to continuously monitor and maintain its course. But that's not where the burrowing rodent's abilities end. The mole rat also has an uncanny habit of burrowing around obstacles—such as ditches or concrete blocks—without ever coming in to physical contact with them. Studying how this is accomplished is very important for human tunnelers and miners. Making navigational mistakes underground is expensive and time consuming, and of course energy consuming. It is estimated that excavating soil uses between 360 and 3,400 times as much energy as moving the same distance above ground [11]

Bats, porpoises and dolphins have biological sonar technology that is vastly superior to anything that man has yet devised. They use sonar to distinguish resolution and identify objects and their material characteristics for objects that are, to all extents and purposes, bewilderingly similar. Researchers in the University of Leicester in the Department of Geology are involved in a project to develop sonar systems based on those animals.

Researchers recording echolocation calls from bats in free flight hope that such technologies will have far-reaching effects in medical and geological imaging, focussing on materials characterisation and non-destructive evaluation. This will particularly apply to the search for oil, gas and other natural resources in rock samples, and may have a role in the waste management industry. Their funding from the Engineering and Physical Sciences Research Council (EPSRC) is intended to apply acoustic
capabilities that occur in the natural world to engineering concepts, such as biomedicine and underwater sonar [12].

It appears that dolphins are able to form very high definition ‘images’ through their sonar feedback and perhaps bats can do likewise. Can this technology be carried further in an application to assist unsighted humans? Perhaps the blind crewman (below Fig. 6) in StarTrek may not be as far fetched a piece of science fiction as once thought. ‘Primitive’ systems are already under development and trial, and perhaps in the not-too-distant future a high definition product may be developed.

![Image of dolphin and sonar feedback](image1.png)

**Figure 6** Can the high definition sonar images of dolphins be applied to help blind people ‘see’? [13][14]

In an important breakthrough in deciphering dolphin language, researchers in Great Britain and the United States have imaged the first high definition imprints that dolphin sounds make in water. John Stuart Reid, and Florida-based dolphin researcher, Jack Kassewitz, has been able to image, for the first time, the imprint that a dolphin sound makes in water. The resulting “CymaGlyphs,” as they have been named, are reproducible patterns that are expected to form the basis of a lexicon of dolphin language, each pattern representing a dolphin ‘picture word’ [13].

3. **THE GECKO STORY**

The Gecko is a lizard whose feet soles are covered with modified layers known as lamellae, each of these is then covered with similarly oriented tiny hairs known as setae. Each setae splits into as many as 1000 branches with spatula shaped tips, measuring a mere 200 nanometers wide. These billions of setae tips create such a vast surface area and are able to nestle so closely with their target surfaces, that the many weak interactions add up to a significant adhesive force.

![Image of Gecko foot](image2.png)

**Figure 7** Gecko Foot inspiring robotic advancement a [15] b, c [16] d [17]
Their grip is so strong that "scientists calculate that a gecko's-worth of setae, which would fit on a small coin could lift about 115 kilograms" (Ben-Ari, 2002). Another way to try and picture it: the combined charge is so powerful that, theoretically you could suspend a 40 kilogram weight from the gecko and they could still get across the ceiling (Robbins, 2001). Therefore in trying to duplicate this wonder scientists concentrate on "the smaller the hairs are, and the more of them you have, the greater the adhesion." (Ron Fearing, engineer at the University of California, Berkeley, as quoted in McDonagh, 2003). [18]

Scientists have discovered that an appropriate arrangement of setae and spatulae held the geckos to the wall by means of a type of a intermolecular attraction known as a van der Waals force. The same force that holds geckos to walls has been used to explain everything from snowflake formation to spider acrobatics.

A bandage based on the gecko grip principal has been developed. Nanoscale features molded into the surface of the adhesive bandage help it bond extremely well. Similar features on the feet of geckos allow the lizards to walk on walls and ceilings. The phenomenon of self-cleaning in gecko setae is surprising because setae are adhesive but can self-clean when dry. Adhesion in gecko setae is a consequence of many divided contact points (spatulae) that deform to achieve intimate, high-density contact with the surface, whereas lotus-like surfaces remain slippery because their rough, and in some cases waxy, cuticle prevents intimate contact. Lotus-like surfaces require water as a cleaning agent, whereas self-cleaning in gecko setae may occur because it is energetically favorable for particles to be deposited on the surface rather than remain adhered to the spatulae. [20]. It is of interest to note that both gecko and lotus-like surfaces become cleaner after contamination for structural reasons; both possess a micro- or nano-rough topology that reduces adhesion with solid and liquid surfaces alike. [21]

There's no gluey stickiness to the gecko's foot, nor does it use suckers or some strange muscular ability - you can detach the part of the foot that gives it the ability to walk up plate glass (harmlessly to the creature - it re-grows like hair) and use it to make "gecko tape" that sticks to nearly anything - instead it relies on a tiny force at the nano-level, multiplied up by the use of a vast number of tiny surface contacts [17]

4. BEES AND OTHER THINGS

Honeybees craft the marvelous structure of the honeycomb (Figure 10) to very high tolerances and specifications. Each cell has two vertical walls, with "floors" and "ceilings" composed of two angled walls. The cells slope slightly upwards, typically about 13 degrees, towards the open ends. There are two possible explanations for the reason that honeycomb is composed of hexagons, rather than any other shape. One, given by Jan Brożek, is that the hexagon tiles the plane with minimal surface area. Thus a hexagonal structure uses the least material to create a lattice of cells within a given volume – maximum volume for minimum materials. Another, given by D’Arcy Wentworth Thompson, is that the shape simply results from the process of individual bees putting cells together: somewhat analogous to the boundary shapes created in a field of soap bubbles. [22]

The closed ends of the honeycomb cells are also an example of geometric efficiency, albeit three-dimensional and little-noticed. The ends are trihedral (i.e., composed of three planes) pyramidal in shape, with the dihedral angles of all adjacent surfaces measuring 120°, the angle that minimizes surface area for a given volume. Tolerances are amazing when considering the dimensions – the worker cell is 5.2 mm across the flats and the drone cell 6.2 mm across, with a cell
wall thickness of 0.073 mm and 0.002 mm tolerance on wall thickness. The honeycomb is indeed a structure of amazing precision and demonstrates the ultimate economy in use of materials and conforms to an arrangement of minimum potential energy. The strength weight ratio is an example to engineers in lightweight wall structure, as in the construction of structural panels in aircraft. See figure 11a. Shown in Fig. 11c is a soap bubble structure between two plates of glass, note the hexagonal structure (minimal energy). 11b would, as a section of dried cracked earth appear chaotic, however the 120° angles are clearly visible, so even in the apparent chaos of cracked earth, nature minimises the energy expended.

5. Fibonacci, Close Packing and The Golden Section

When the Italian mathematician Fibonacci discovered that the number series for which he is now famous, the implications of this in relation to design were poorly understood. Even now this mathematical number series is to be found again and again in design. It produces a close packing solution, a proportion such as that found in the nautilus shell, the sunflower, the pattern which the leaves grow in order to expose them to sunlight, or the ever pleasing aesthetic of the golden rectangle as seen in Figure 12.

This proportion has been used aesthetically in art and architecture from the Greek Empire right to this day. It is an inspiration for engineering design problems such as less noisy and significantly more efficient electric fans. In the nautilus shell it is not just the Fibonacci curve which in itself is beautiful, but each chamber appears to increase in volume in a 1:1.618 ratio. There is indeed an infinite source of exemplars to be found in nature.

6. CONCLUSION

As we strive to combat global warming, develop sustainable energy systems, protect the environment and Earth’s eco-systems, we have at our disposal in the natural environment all the exemplars we need.
Companies are beginning to see the possibilities as they look to nature for design inspiration. Recently the Mercedes Benz motor company built an aerodynamically efficient family car based on the hydro-efficient boxfish, see Fig. 13 below. This paper has only discussed a few of these designs, and not even in minute detail. It behooves engineers and designers to look closer at such a rich pool of inspiration.

When DaVinci said that “in her inventions nothing is lacking and nothing is superfluous” he was accurately describing design in nature.

Now, innovation has never been more necessary, so whether we look to the great rainforests or the humpback whale, or the recently discovered flagella motor, which is just 20 nm across, (a fraction of the diameter of a human hair). This complete motor, which is described as a machine of ‘irreducible complexity’, has serious potential in nano-medical treatment and investigation. This “outboard motor”, which is used by bacteria to propel through liquid, as its propeller rotates at 400 times per second, gives us some insight as to what is possible when nature is observed under the microscope. It can be said with certainty that nature is lean, just-in-time, the ultimate problem-solver, and the perfect exemplar in sustainable engineering, and is indeed an inspiration for intelligent and innovative engineering.

Environmental Management Systems in Smaller Enterprises

(Problems and Solutions)

Mike Gallagher, William Gaughran and Pat Phealan

Department of Manufacturing & Engineering,
University of Limerick
Ireland

ABSTRACT

On average SMEs represent over 90% of all enterprises and account for 50-60% of employment at an Irish level. SMEs are particularly important in supporting economic growth and livelihoods in countries. Small enterprises in particular form the back bone of the Irish economy, with eighty-two percent of all industrial enterprises in Ireland classified as ‘small.’ Of which, 95% are Irish owned employing between three and forty-nine people in 2004. [1] Due to their size, location and ownership SMEs have been seen to be embedded in their communities. This brings with it a level of acceptance by their stakeholders, and in particular a certain neglect toward their environmental performance. This coupled with the reality that SMEs are less likely to be subjected to rigorous inspections in relation to environmental standards, forms a type of comfort zone in which many wait and detracts from the real truth of the environmental situation. In various forms SMEs learn from larger companies, for example business management systems are tailored for the larger companies and do not fittingly suit SMEs. [2] This holds true for environmental management as unlike large companies, SMEs do not have the expertise or resources to implement a formal management system successfully. [3] Studies confirm the larger the company the more likely it is of having an EMS implemented [4] This paper will identify & discuss the barriers that face SMEs in implementing a formal EMS, in particular ISO 14001. The initial stages of research currently undertaken in developing a strategic framework for SMEs in achieving sustainable development are discussed. SMEs and their current impact on the environment is examined, supplemented by regional survey results focusing on a sector specific case studies addressing SMEs current awareness and practices. EMSs, their origin, structure, motives for adoption results and finally progress to identifying the precise barriers that exist for SMEs in achieving ISO 14001, is also discussed.

1. INTRODUCTION

Individually SMEs impose negligible stress on the environment however collectively their impact is considerable. Some researchers have suggested that SMEs could contribute up to 70% of all industrial pollution (although this is not irrefutably supported by evidence). [5] In their annual report ‘SMe-nvironment’ on the environmental performance of British SMEs - NetRegs state that “the smaller a business is, the lower its level of environmental awareness and the less likely it is to take action to address it’s environmental impacts.” [6] SMEs operate quite differently to one another when it comes to environmental practices. Palmer and Hillary (2000) classified SMEs in the manner in which they dealt with their environmental performance. [7]
These stages categorised SMEs environmental activity/inactivity. However, it still provided a rudimentary understanding of the actions of the SMEs. With the majority of SMEs classified as ‘inactive’ [8] along with the heterogeneous nature of SMEs it is difficult to draw any generalisations into:

1) practices or principles
2) environmental performance levels,

employed by SMEs within any of these stages. To assist SMEs in reaching the latter stages of ‘managed’ and ‘standards’ e.g. ISO 14001, it is imperative we identify firstly the barriers experienced, and secondly develop tools to overcome such grievances. SMEs represent an array of assorted sectors, environmental impacts that exist in one sector may not be the same in the other. In order to achieve the above objective we must hone in on the properties of a particular sector and then project them onto general findings. [9]

WOOD MANUFACTURING SECTOR [ENVIRONMENTAL PERFORMANCE]

As well as lagging behind their larger business counterparts in regard to their environmental performance wood manufacturing SMEs have also been seen to lag behind alternative sub-sector SMEs in surveys conducted in the UK. [6] Their poor environmental performance is supported from results received from an Irish regional study undertaken in late 2007. The purpose of the Irish investigation was to gather, interpret and ascertain regional and sector specific information regarding, Irish Timber Frame Manufacturing (TFM). The study established SMEs current knowledge and practices relating to the environmental issues. The majority of SMEs have a workforce of below fifty employees with the mean average calculated at 38 employees. This classes 68% of the study within the EU’s definition of a ‘small enterprise’ supporting the prevalence and importance of small enterprises. Fig. 2 illustrates the number of SMEs participating in listed environmental performance measures. There is not one measure, including recycling, in which they all participate. There is a severe lack of activity when it comes to TFM SMEs implementing simple measures to curb their negative environmental impacts (NEI). This is supported by 88% not responding to a question directed toward the NEI activities they perform. Either 88% of TFM SMEs do not commit any of these activities, though this is unlikely, or a very high percentage carry out these activities not wanting to admit it on paper the latter being a more realistic conclusion. The detrimental activities that cause NEI were as follows:

- Store chemicals oils or fuel
- Produce and or import packaging
- Use water pumped from lakes & rivers
- Emit smoke or fumes
- Discharge to water course or sewer
- Store waste

![Figure 2. Environmental Measures Undertaken by Irish TFM SMEs](image)
In relation to EMSs, 27% of companies within the Republic of Ireland had a type of EMS, in contrast to 67% in Northern Ireland. Suggesting that NI TFM’s have a deeper knowledge and understanding of EMSs and considering the degree of similarity in business to their Irish counterparts, a superior environmental performance. To breakdown the results of the different EMSs further:

- 0% had ISO 14001,
- 12% have BS-8555 EMS implemented,
- 20% have either an in-house EMS or an unspecified EMS,
- 28% would like to implement an EMS
- 40% do not want to implement any type of EMS.

96% of respondents requested to receive a summary of the survey signifying a high level of interest into environmental performances and practices of their competitors/colleagues. However, it does not take away from the fact that SMEs and in particular wood manufacturing SMEs, are an environmentally poor performing sector.

2. ENVIRONMENTAL MANAGEMENT SYSTEMS

To identify and fully comprehend the difficulties SMEs experience during implementation, a firm understanding of the EMS is essential. It is beneficial at this stage to explain the origin, structure, and actions experienced through the implementation of a formal EMS are examined in the context of this sector specific investigation.

An EMS is a set of management procedures to analyse, control, and reduce the environmental impact of a company. An EMS is said to be appropriate for all types of organizations of varying sizes. Starkey (1998), defines an EMS as consisting of a number of interrelated elements that function together to achieve the objective of effective environmental management. [3] Environmental management began in North America in the 1970’s in response to stringent and fast-growing environmental legislation. [10] A plethora of in-house EMS followed until the first attempt of standardization arose in 1992, when the British Standards Institution introduced BS 7750. This was the first environmental management standard ever, [10] it was drafted from the English equivalent of ISO 9001 and BS 5755 [11] BS 7750 was soon adopted as a national standard by various countries, e.g., Denmark and the Netherlands. From BS 7750 EMS various environmental management national standards were created, e.g., the French X30-200 and the Irish IS 31. [10]

In a growing mismatch of national EMSs in the early 1990’s, there was a need for a European or international standard. This was the origin of the two current formal EMSs - ISO14001 and EMAS. Companies now had the ability to choose from European and/or an International standard of environmental management and inevitably the national standards and in-house EMSs fell to the wayside - with the original EMS BS 7750 being withdrawn in March 1997. [10] EMAS certifications are much lower than ISO 14001 and this position is likely to remain with its popularity peaking in 2001. [12] Certifications of ISO14001, which became effective after EMAS, are now currently greater than 32:1. [10] Re-affirming its status as the world’s most recognized and prominent EMS.

**EMS ISO 14001 STRUCTURE**

The majority of EMSs is derived to some extent from the ISO 14001 model. The model is based on PDCA cycle first developed by deeming. The Plan –Do –Check –Act cycle’s repetition gives life to standards ability to achieve continual improvement. The model forms the structural framework to the standard the framework has five mandatory parts. [13]
Environmental Policy: Creation of an ethos for the organisation as a whole, specifying its commitment to continual environmental improvement.

Plan: establish the objectives and develop the processes necessary to deliver results in accordance with the organization's environmental policy.

Do: implement the processes.

Check: monitor and measure processes against environmental policy, objectives, targets, legal and other requirements, and report the results.

Act: take actions to continually improve performance level of the environmental management system. [3]

What has an EMS to offer and what are the main reasons for EMS adoption? It firstly enables a company to become compliant to all relevant environmental legislation. Building on this it offers the company increased efficiency and finally it reduces costs and provides for greater operational consistency. Table 1, sourced from work by Hallinan and Starkey, provides a comprehensive list of benefits experienced by SMEs. [3, 8]

<table>
<thead>
<tr>
<th>Cost Savings</th>
<th>Cost savings can be achieved through a number of ways such as introducing more efficient processes, and thus reducing waste or resource usage, such as raw materials or electricity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ensuring legislative Compliance</td>
<td>By ensuring legislative compliance, the company can avoid possible fines for non compliance</td>
</tr>
<tr>
<td>Anticipating future Legislation</td>
<td>By anticipating future legislation a company can take time in taking investment decisions instead of a more costly last minute drastic change.</td>
</tr>
<tr>
<td>Reduced Environmental Risk</td>
<td>Undertaking principles by certain Environmental Management System (described later), environmental risk can be reduced possibly improving relations with investors who base their decisions on risk.</td>
</tr>
<tr>
<td>Meeting Supply chain requirements</td>
<td>More and more companies are demanding that their suppliers adhere to certain environmental standards, and if these are not met, the company will most likely lose their contract. Thus, environmental management can help SMEs stay in business, and gain new contracts.</td>
</tr>
<tr>
<td>Improved relations with regulators</td>
<td>When a company shows a good level of environmental management it is possible that the regulatory bodies take a ‘nicer’ approach to them e.g. a reduction in the number of inspections per year.</td>
</tr>
<tr>
<td>Improved Public Image</td>
<td>Environmental concerns are becoming more and more important for customers and hence a company can improve its image by publicising its environmental activity.</td>
</tr>
<tr>
<td>Increased Market Opportunities</td>
<td>A combination of the above factors such as reduced costs and improved public image can open new market opportunities.</td>
</tr>
<tr>
<td>Employee Enthusiasm</td>
<td>As the environment its becoming an increasing concern in recent times, employees are often very enthusiastic that they can contribute towards improving environmental performance</td>

Table 1 EMS benefits/advantages (Source Cross 48, 76)
Currently Formal EMS adoption is below 0.5% of all European SMEs. [14] Figure 3 by Russomanno perfectly illustrates the motives behind, the barriers that present themselves and the results that are realised through the adoption of a formal EMS. [15] Motives for adoption may be categorised into two group’s intrinsic and extrinsic motives. Studies reveal the majority of SMEs are pressurised to adopt ISO 14001 through extrinsic motives such as stakeholders, supply chains pressure, etc. [5] This type of adoption is harmful as there is an unwillingness on behalf of the management and employees to implement the EMS and sometimes has been seen to hamper the effectiveness of the EMS. [9] Some of the benefits within the table e.g. employee enthusiasm and improved public image are regarded as intrinsic motives. It is interesting to note that some Irish TFM SMEs who extrinsically adopted an EMS realised intrinsic benefits through its implementation. This reflects a repeating theme in the research of environmental management that a severe lack of knowledge by the SMEs leads to fallacious assumptions of the standard and what it truly can achieve. [9] This is further more supported by Irish findings were companies without any type of EMS suggested that ISO 14001 offered extrinsic benefits only with some stating it provides no benefits at all. On the other hand companies with an EMS, and therefore hold a level of environmental management knowledge, provided a list of both intrinsic and extrinsic benefits.

To counteract this lack of knowledge many seek external assistance. [14] A TFM SME who received such assistance believes that without it achieving BS 8555 (a type of EMS) would have been unattainable for them similar SMEs. Figure 3 [8] and other studies discussed also identify SMEs lack the necessary financial requirements to achieve a similar environmental feet as their larger counterparts [3] On a comparison study of implementation barriers experienced by SMEs in Hong Kong, Canada and globally lack of ‘environmental knowledge’ and ‘financial cost’ all appear in each list of top barriers. [14] [16] [17] Understanding 80% of SMEs implementing ISO 14001 opt for external assistance this brings its own notable financial problem. [14] As many have difficulties in obtaining appropriate subsidised or free assistance. In Hong Kong 90% of SMEs that sought external help choose professional consultants. [17] While in the global study 63% of the companies cost in employing consultants was covered solely by enterprises. [14]

It is clear that two of the top four barriers ‘cost’ and ‘lack of environmental knowledge’ spring from the same problem that being lack of environmental management knowledge. Therefore addressing knowledge without the use of external consultants may provide a fundamental basis for an achievable EMS however further research into the methodology to achieve this is required. The lack of expertise in the area of environmental management is just one example of an area in which SMEs struggle. The characteristic well sighted for an SME, of having a lack of financial assets in relevance to their larger counterparts may originate from a lack of knowledge in many business areas thus having to seek costly external assistance. [3] Figure 3 lists other barriers that also feature within those studies listed.
ISO 14001 PROBLEMS & SOLUTIONS

Previous research has already highlighted the low uptake of ISO 14001 by SMEs and in particular by Irish SMEs. [18] [13] It is evident from this the standard has some defects. Although ISO maintain the standard is viable for all company types and sizes [3] the process of its feasibility, continual improvement, is a dubious process based upon an organisation’s own set objectives/targets. The process of ‘continual improvement’ has created much ambiguity amongst SMEs with McDonald 2003 noting the standard creates “…vagueness, as the work often relies on vague guiding principles of “continual improvement” [19]

ISO issued a guidance document to assist implementation, ISO14004. While the guidance was created for use by all size organisations ISO recognises, “the importance of SMEs and this guideline [ISO 14004] acknowledges and accommodates the needs of SMEs” [3] to some extent confessing the standards incongruity to SMEs. ISO 14001 was revised in 2004 and although some of the revised elements are easily understood, SMEs continue to have difficulty in;

1) auditing and identifying their environmental impacts
2) setting their objectives and targets, [3]

which are core areas in achieving continual improvement. These were the precise areas adapted from the successful ISO 9001 standard and blended into the revised 2004 version yet research reveals difficulties still remain. Other problems experienced is a heavy burden of paper work [14] [16] “a long paper trail exists in the certification process and many small companies do not have the time and staff resources in dealing with these onerous documents”. [20] This coupled with the lack of environmental awareness of staff [14] and sector specific tools depicts a losing battle for SMEs and provides ample reasoning in seeking third-party professional consultants. [15]

4. DISCUSSION

This section focuses on three areas, all of which are interrelated, where ISO 14001 overlook SMEs in achieving the standard. BS8555 a British standard EMS was developed to help businesses, SME’s in particular, to adopt an EMS in the most efficient and pragmatic manner, with an underlying objective to cause no upheaval to business activity. [6] The reasoning behind this EMS originated from the very low uptake and frequent failure of SMEs in implementing formal EMSs. [10] During its design inception it listened to the demand frequently expressed by SMEs for ISO 14001 to broken into various steps. BS 8555 drew from the success of ISO 14001 over EMAS noting that flexibility during implementation was of utmost importance for businesses. “EMAS is more rigorous than ISO 14001, it demands more”. [10] The workload of SMEs can fluctuate immensely in short time spans and they can be overburdened with work in the space of a couple of days. BS 8555 understood this and developed an EM system to adhere to fluctuating business workloads by incorporating phases of implementation. SMEs benefit from a phased system as it offers a withdrawal opportunity at anytime and in doing so provides external certification recognition of their efforts up to the phase of withdrawal. [21]

The strict onerous structured workload in ISO 14001 with no intermediate stages presents another problem. The success of many SMEs has been closely associated to the type of culture that exists within the particular SME. [22] Culture maybe described as what an average employee would feel inside the factory walls on a day to day basis. In the Organisational Science Journal, work culture was found firstly to be measurable and then to be directly related to important organisational outcomes, similar to that to the success of an EMS. [22] An SME in England stated that the BS 8555 allowed “A degree of flexibility which ensures the EMS works for the company – not the other way round” This flexibility generated by the stages in implementation allowed the particular EMS to become part of the ‘organisation’s culture’. [23] Pointing out that the 14001’s rigid work-intensive structure is detrimental in two ways. It firstly overloads the workloads of the employees attempting to implement the stand. While secondly its rigidity tightness an organisations culture reforming it to hamper and ultimately reject the management system. Unveiling the close association of ‘positive culture’ and ‘EMS success’ an idea which Kirkland and Thompson (1998) reiterate by suggesting corporate culture is important in determining the success of an EMS [24]
5. CONCLUSION

This paper has identified a sector that contributes significantly to negative impacts on the environment. SMEs are often overlooked when it comes to environmental finger pointing for a number of reasons. SMEs firstly are embedded in their local community and due to these close ties it is not surprising a level of acceptance is granted. While secondly owing to the nature of their business and size it is suggestive that little environmental impact occurs. Employing an average workforce of under 40 employees and manufacturing a renewable material, the TFM industry seem to impose negligible stress on the environment. However studies reveal that collectively the particular sector was found to be one of the poorest performing.

EMSs have been around for a number of decades their evolution into standards has unveiled ISO 14001 to be the most implemented and recognisable standard internationally. The standard initially tailored for larger companies and is not ideal for smaller enterprises. Indisputably many benefits are realised through EMS implementation. Case study examples have revealed Irish TFM to experience both internal and external benefits, while companies without any type of EMS suggest ISO 14001 would apparently offer little or no benefit at all to their business. This particular example underlines the key barrier of SMEs in first adopting, and secondly implementing an EMS a lack of knowledge on behalf of the SME. Comparison studies reveal ‘lack of environmental knowledge’ and ‘lack of finance’ as being the main obstacles in successful EMS implementation. Further investigation exposes ‘lack of finance’ is experienced through SMEs paying for professional consultants due to their …. lack of environmental knowledge!! When it comes to EMSs SMEs have a distinct lack of knowledge on the ‘environment’ and ‘management systems’. Unfortunately for SMEs ISO 14001 exacerbates these troubles.

The standard’s specific problems are four fold;
1) Auditing and identifying environmental impacts
2) Setting objectives and targets
3) Onerous Paperwork
4) Adherence to rigid structure

To accomplish the first two obstacles, SMEs currently turn toward external assistance a costly avenue for cash strapped SMEs. Case studies reveal seeking such professional assistance has been the thorn in many attempts of implementation due to the financial implications it presents. For SMEs to receive such assistance and tutoring without the use of costly consultants would represent not only a pragmatic answer but an intelligent one. Such a development is further complicated by the heterogeneous nature of SMEs. Environmental impacts for one industry may not be the same for another and therefore as a consequence their objectives and targets will also differ. On-going research similar in nature to the author, in developing sector specific tools to assist in EMS implementation provides the solution.

BS 8555 is a welcome development for SMEs in the field of environmental management. Tailored for SMEs it identifies the immense amount of paperwork necessary for ISO 14001 as a problem for the already multi-jobbed employees. Instead it exploits a workbook strategy that includes template sheets, case studies and checklists. The BS 8555 standard has seen immense growth in Europe with ISO’s technical committee overseeing ISO 14001, TC207, taking note of this growth and it’s suitability to SMEs in a recent meeting entitled ‘Be-aware! Small scale EMSs eventually might grow up.’

It is evident ISO 14001’s rigid structure does not accommodate SMEs, whose workload can fluctuate in such short time spans. Once implementation of ISO 14001 is undertaken it is all or nothing for SMEs with the latter occurring much too frequently. BS 8555 provides a route to ISO 14001 with a number of stages/phases on the way, providing an SME the opportunity to gain recognition up to the point of withdrawal. Positive culture has been identified as an integral attribute to EMS success. This structure allows the EMS to work for the company and not the other way around thus allowing it to become part of the organizations culture. EMAS is currently being revised with the new standard ready in 2010. The new standard will include a more objective/achievement orientated scheme and be simplified implementation into phases. This new model reflects the thoughts and findings in this research and shines a light on the future direction of Environmental Management Systems.

Using biofiltration to clean waste gases

ABSTRACT
The paper gives an overview on the ways to clean waste gases using a variety of technologies. Emphasis is placed on biological processes. Some guidance is presented on how to model the behaviour of a biofilter used to remove styrene and acetone from air. The experimental data showed the inhibitory effect of the inlet acetone level and a new model to represent this is outlined.

INTRODUCTION

The cleaning of waste gases can be achieved by a number of physical and chemical approaches, including incineration, adsorption, scrubbing and condensation. Incineration may involve the consumption of extra fuel and in certain processes, may be catalytically enhanced. Adsorption onto solid beds of substances like activated carbon is also a possibility but usually the captured waste gas has then to be separated from the bed (by heating or a change in pressure etc.) Contacting the gases with a absorbing liquid is a common approach eg using caustic soda or amine solutions, but, as in the case of adsorption, regeneration may also be required. The condensation option is attractive when the gaseous waste stream is a valuable substance and a cheap cooling supply is available. However, there are a number of ways of approaching this worthwhile task using microbial action.

A biofilter is an example of such a process, see figure 1. It typically comprises a cylindrical or rectangular vessel through which the dirty gas passes. Within it, there is a solid bed of perhaps, natural material such as soil, compost, heather or activated carbon. However, plastic or glass packings having a high surface area are also commonly utilised. A colony of micro-organisms grows on the (moist) surfaces of these solids. As the gas mixture passes through the bed, the volatile organic compounds dissolve in the water and are then digested by the bacteria and/or fungi. Using these devices removal efficiencies of 90+% are possible, provided that the bed is sized correctly and the micro-organisms are kept in a healthy state.

*corresponding author: Tel: +44 (0)1642 342499; Fax: +44 (0)1642 342401; E-mail: a.m.gerrard@tees.ac.uk
The process works by the microbiological digestion of the odour-giving compounds as the gases pass through the packed bed. See reference [1] for an excellent summary of the subject. It is usually assumed that the VOC first dissolves in the liquid film surrounding the solid packing and then diffuses through it. As it does so, the resident microbiological organisms digest the pollutant, forming water and carbon dioxide. There is little cell growth in the bed, indeed if there is, then blockages can be a problem! The process is modelled by considering diffusion with bio-chemical reaction in the liquid phase, coupled with convection in the gas phase. The bio-reaction kinetics can be quite complex but they are often assumed to be zero or first order, (when analytic solutions can be found, see theory section). When the device is running in an unsteady state condition, then adsorption has to be included in the model.

**PRACTICAL DESIGN RULES**

If you are considering biofiltration as a possible solution to an odour problem, then the following ideas may be useful:

Low concentrations of VOC (typically tens to hundreds of ppmv) and high gas volumes favour this technology.

The overall removal efficiencies are often of the order 60-95 percent, hence if practically total removal is required, then this may not be an appropriate process. However, for easily biodegraded substances the efficiency, especially under laboratory conditions can approach 100%, (2). Mildenberger and van Lith [3] describe a very large biofilter at a sewage water plant which achieved 80% removal over a long period.

When removing sulphur compounds such as hydrogen sulphide, methanediol, dimethyl sulphide and others, good results have also been obtained using *bio-trickling filters*. (These are biofilters where there is a an additional continuous liquid stream passing down the bed to keep it wet at all times.) A reason for this is the much better pH control because of the circulating aqueous medium (the pH decreases due to the sulphuric acid formation in bio-oxidation process). The ability to keep the pH below 3 achieves almost total removal, even though the odour threshold concentrations of the sulphur compounds are around 15 ppb. In addition, the pressure drop across these beds are lower than those in biofilters due to different packing materials used, such as plastic Pall rings being used.
Two parameters are often used to get a rough sizing of the biofiltration unit. The first is the elimination capacity, EC, defined as the mass of VOC or odour removed per time per volume of bed. Appendix B of reference [1] suggests a range of values around 10-300 g m$^{-3}$ h$^{-1}$.

The other parameter is the empty bed residence time, $\tau$, which equals the volume of the empty bed divided by the volumetric flow-rate. This usually has a value in the range from a fraction of a minute to a few minutes. Because of the complexity of the biological and physical processes going on in the bed, the design process usually requires previous experience together with laboratory or pilot scale investigations.

The pressure drop across these beds is quite low e.g. a few centimeters water gauge, but it can rise if the bed collapses with age, or there is excessive cell growth.

A major operating variable to control is the moisture content of the filter, if the bed dries out too much or is too wet, then this threatens the viability of the micro-organisms present. (The feed stream can be humidified by spraying in water.) As mentioned before, the material used for the (moist) packing can be a natural material such as soil, peat or heather which have a naturally occurring microbial population. Activated carbon, perlite and plastic packings are also used, often with better mass transfer and pressure drop characteristics. The microorganisms can also be specially selected and optimised for a given separation task and are then introduced into the biofilter.

Broadly speaking, these devices work best when the conditions are steady i.e. flow-rate and inlet concentration remain within reasonable bounds. They can recover from sudden peaks and troughs, but this can take time. A more serious disturbance occurs when the supply of feed is cut off completely for a period. (There is then a danger that the microorganisms might die, if the interruption is sufficiently long.) Some systems require the periodic addition of nutrient solutions to supply the microbes with essential nutrients which ensure that they have sufficient catabolic activity for pollutant degradation, but this is usually not needed with natural packing materials.

On full-scale units, maintenance is needed to keep the spraying system in good order. Sometimes, the bed needs to be emptied and repacked to re-establish the original (lower) pressure drop and to redistribute the microorganisms. (There is some evidence that, after a while, there is a greater population of bugs at the inlet end of the filter and hence some of the rest of the bed volume may be running at a lower removal efficiency.

Overall, there is growing evidence [4] that a carefully designed and operated biofilter is capable of removing the majority of odour from a wide range of air streams including those found in water and sewage plants.

**THEORY AND RESULTS**

We shall now turn to a particular application of this process, the removal of styrene and acetone from air. Laboratory data collected in Prague has shown that both of these chemicals can be effectively removed by biofiltration but that the bugs have a marked preference for digesting the acetone rather than the styrene. Indeed, higher inlet concentrations of the more easily broken down acetone actually slows down the rate at which the styrene is removed. Simple models can be suggested to represent the removal of each substance. But better predictions of the performance of the biofilter arise when we also study the interaction between the two compounds. We have been able to model this behaviour, so that a rational way of sizing these devices can be attempted.

Ottengraf [5] has shown for “piston flow” conditions with no interfacial resistance that three analytic models may be derived. By assuming either “zero order” kinetics, (that means the rate of biological reaction is independent of the concentration of the pollutant concentration), then there are two cases here depending on whether the reaction or the diffusion is the slower (or “controlling”) process, the results are given by equations (1) and (2). His third model assumes first order kinetics, where the rate of reaction is proportional to the waste gas concentration, see equation (3). These three models offer a convenient way to linearise the expected concentration profiles, $C_G$ down the length of the bed, $h$.

\[
\frac{C_G}{C_{Gin}} = 1 - \left( \frac{h \cdot K_0}{C_{Gin} \cdot V_u} \right)
\]

(1)
\[
\frac{C_G}{C_{Gin}} = 1 - \frac{h}{v_a} \cdot \sqrt{\frac{K_v \cdot D_{ef} \cdot a}{2 \cdot m \cdot C_{Gin} \cdot \delta}}
\]

(2)

\[
\ln \left( \frac{C_G}{C_{Gin}} \right) = -\frac{h \cdot K_v}{m \cdot v_a}
\]

(3)

(The other parameters in the equations are usually combined into a constant whose value is found experimentally.)

For example, the new, pure styrene data was analysed first by studying linear, square root and logarithmic graphs of the measured concentration plotted against bed height. (The styrene concentration was measured at five points down the bed.) For a bed consisting of activated carbon, the best fit (i.e. highest coefficient of determination, \( r^2 \) and the lowest coefficient of variation of the rate constant (defined by the standard deviation divided by mean,) was given by the first order kinetics model. See figure 2 for an example, where the log-linear graph confirms the appropriateness of the first order assumption, using equation (3).

(For the perlite bed, zero order kinetics with diffusional limitation was slightly preferred, as shown by a good fit to a square root of concentration versus bed position graph.)

Then, the data on the mixture of styrene-acetone-air was studied to measure the interaction effect.

The experiments were organised with a constant air flow-rate and a constant inlet styrene concentration. Then the acetone inlet concentration was gradually increased from a low to a high level. There is clear experimental evidence that the two VOC’s (styrene and acetone) influence the rate of removal of each other. The removal efficiency of (the more difficult to digest) styrene progressively declined as the acetone inlet concentration increased. The acetone removal also declined with its increasing inlet loading. See figure 3.
Following a similar approach to the pure styrene analysis, first order kinetics seemed to fit best for both the styrene and the acetone removal rates when each was modelled independently of the other. However, there was a steady decrease in the value of the fitted rate constant (for both styrene and acetone) as the inlet acetone concentration increased. This interesting behaviour can be modelled as follows.

**NEW MODEL**

If we assume the acetone follows first order kinetics with some self-inhibition then:

$$\frac{dCa}{dh} = -B_1 \cdot Ca \cdot (1 - p \cdot Ca)$$  \hspace{1cm} (4)

where $p$ is the inhibition constant.

This can be solved to give:

$$Ca = \frac{Ca_{in} \cdot \exp(-B_1 \cdot h)}{[1 - p \cdot Ca_{in} \cdot (1 - \exp(-B_1 \cdot h))]}$$  \hspace{1cm} (5)

The digestion of the styrene is also assumed to be first order and to be inhibited by the presence of the more easily digested acetone (which is preferentially consumed by the micro-organisms.)

$$\frac{dCs}{dh} = -B_2 \cdot Cs \cdot (1 - p' \cdot Ca)$$  \hspace{1cm} (6)

This can be integrated:

$$Cs = Cs_{in} \cdot \exp\left(-B_2 \cdot \int \left[1 - \frac{p' \cdot Ca_{in} \cdot \exp(-B_1 \cdot h)}{1 - p \cdot Ca_{in} \cdot (1 - \exp(-B_1 \cdot h))}\right] \cdot dh\right)$$  \hspace{1cm} (7)
(The remaining integral in equation (7) can be solved analytically but it is more convenient to solve it numerically using the Trapezium rule.)

Then the parameters $B_1$, $B_2$, $p$ and $p'$ were altered to give the best fit to the measured concentration profiles of acetone and styrene down the bed’s length. The following table gives the best values found.

### Table 1: Optimal values of $B_1$, $B_2$, $p$ and $p'$ parameters.

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>$B_1$</td>
<td>3.6</td>
</tr>
<tr>
<td>$p$</td>
<td>0.00083</td>
</tr>
<tr>
<td>$B_2$</td>
<td>3.85</td>
</tr>
<tr>
<td>$p'$</td>
<td>0.00093</td>
</tr>
</tbody>
</table>

When these values are put into equation (7), then the performance of the biofilter can be modelled. Figure 4 shows the actual and predicted data.

![Figure 4](image_url)

Figure 4 is a scatter diagram to show the adequate fit of this model to the experimental data.
CONCLUSIONS

Biological processes are well worth considering for cleaning industrial waste gases. Usually practical experience and laboratory data are needed to design these devices. The new experimental data on the styrene-acetone-air system showed that the acetone inlet concentration affected both its own removal rate and that of styrene. A new model has been proposed to describe this process.

NOMENCLATURE

- $B_1, B_2$: kinetic parameters
- $C$: gas concentration, g.m$^{-3}$
- $C_{i}$: inlet gas concentration, g.m$^{-3}$
- $h$: filter bed height, m
- $p, p'$: inhibition parameters

subscript
- $i_{in}$: inlet condition

ABSTRACT

Supply enormously outstrips demand in the current corporate environment, market competition is growing and the struggle for customers is growing in intensity. Companies have to face up to new and even stricter environmental legislative requirements. Steadily increasing prices of raw materials and energy are another threat for many companies. Last but not least higher customer requirements have to be satisfied. Companies need to differentiate themselves from their competition. However, one can differ only in what is not obligatory for others, i.e. what is voluntary. Some companies have already learnt that there are some activities not required by regulations that, despite being voluntary, are not useless. Voluntary environmental activities can become a significant competitive advantage factor which creates market differentiation.

1. INTRODUCTION

1.1 PREVENTIVE VERSUS REACTIVE STRATEGIES

Many forms of preventive as well as reactive strategies for environmental conservation are being used in industrial engineering.

Cleaner production, ecodesign and ecolabelling are examples of preventive strategies. As the name indicates the preventive strategies endeavour to prevent the origin of damage, they seek for sources of pollution and waste. Preventive strategies have more potential and their realization should be supported. The reason why reactive strategies are not so effective or promising is the fact that they do not focus on the sources of environmental damage, they only try to mitigate the consequences of production. Among these “end-of-pipe” technologies are, for example, refuse compactors, collection containers and vehicles, waste heat recovery systems, air pollution filters, noise abatement investments and sewage treatment plants. As a result the quantity of toxic agents in one environment domain drops, but rises in another domain. As practice has shown, the preventive strategy has a positive impact on the environment and it leads to financial savings, economic profit, cost reduction and enhancement of the competitive advantage at the same time. Preventive strategy is therefore considered as a double profit strategy: environmental and economic – a so called ‘win-win’ strategy.

Companies have a lot of voluntary environmental instruments at disposal. There are two types of voluntary environmental instruments: regulative and informative. Among the most obvious voluntary instruments are cleaner production, ecodesign and ecolabelling.

2. CLEANER PRODUCTION

2.1 CONCEPT OF CLEANER PRODUCTION

¹* Tereza Kadlecová: Tel.: +420 377 638 464; Fax: +420 377 638 402; E-mail: fidlerot@kpv.zcu.cz
The concept of cleaner production is being connected with the integral preventive strategy which is applied especially to the sector of production. The aim of this strategy is to do away with the causes of environmental pollution as a consequence of production.

Within cleaner production the material and energy flows are monitored in order to identify the sources of undesirable waste. Afterwards the possibilities of elimination of these sources are explored, namely:

1. Ease of technical feasibility;
2. Final economic efficiency;
3. Environmental efficiency.

All the company processes are observed as a whole - in terms of impact on all domains of the environment. It is therefore not possible to transfer the negative impact from one domain of the environment into another one, as it is with the end-of-pipe technologies. The implementation of cleaner technology in a company is not a one-shot action, but it is a long-term process. Effectiveness is the reason why a company should deal with cleaner production. In other words, reducing raw material and energy consumption reduces the negative impact on the environment. Waste increase is thus being prevented at the source and this leads to a significant economic effect at the same time.

The main features of cleaner production are:

- preventive approach to solving the problems;
- integration principle;
- wide range of application (processes, products, services);
- economic benefits.

Type of product, technology used, machines and equipment, raw material, work organization and adherence to the manufacturing processes are all controlled as part of cleaner production.

2.2 CLEANER PRODUCTION SPHERE OF INTEREST

Cleaner production, as a preventive strategy for environmental conservation, focuses on searching for the origin of waste. In the cleaner production main sphere of interest are:

- product character,
- technology used,
- machines and equipment,
- raw materials,
- adherence to manufacturing process principles,
- work organization,
- employees approach to the tasks,
- company management system.[1]

In the above examples the impact on the environment can be reduced by engineering as well as non-technical (organizational) methods, which are very effective and are no or very low costs in many cases.

One can prevent waste origin by:

a) better production logistics and work organization – this is the most convenient economic option (e.g. careful treatment with the raw material,

b) technology changes – simple machines adjustments, changes in methods principles,

c) change in main material,

d) product chase – e.g- reduction of materials used for production,

e) waste restoration in the same process where it arose, so called reverse waste,

f) waste recycling in the same company.[1]
2.3. CLEANER PRODUCTION IN THE CZECH REPUBLIC

Cleaner production activities began in the Czech Republic in 1992. However, the application level of cleaner production is in practice rather low, as can be seen in the following figure.

![Figure 1: Number of cleaner production projects in years 2002 - 2004](image1)

3. ECODESIGN

3.1. CONCEPT OF ECODESIGN

Ecodesign is one of the preventive oriented voluntary regulative instruments of environmental policy. While cleaner production focuses on a company as a whole, the concept of ecodesign concentrates on product development and design.

Ecodesign incorporates requirements of environmental protection into product design and development. So far there is no unified definition of ecodesign. In general, ecodesign can be defined as a systematic process of product design and development which puts emphasis not only on classical features such as functionality, economics, safety, ergonomics, technical feasibility, aesthetics, but it also puts emphasis on the minimum negative impact of a product on the environment.

![Figure 2: Influences on product design and development, [4]](image2)
The main purpose of ecodesign is to design a product with a minimum impact on the environment in its own life cycle (“from cradle to grave”).

Within ecodesign all phases of the product life are considered, especially:
- getting raw material;
- production;
- usage;
- disposal.

This means that the method of disposal is considered during product design. It is therefore the most preventive and economical approach towards the mitigation of a product’s negative impact on the environment.

Outlines of ecodesign are as follows:
- enforcement of safe products and services,
- preservation of biosphere,
- sustainable usage of natural sources,
- minimize waste and increase recycling,
- wise energy utilization,
- reducing environmental and health hazards to employees and customers,
- exchanging of information among the eco-designers. [5]

### 3.2 TYPES OF ECODESIGN STRATEGIES

1. Development of a brand new product concept
2. Change in product construction,
   a) Strategies focusing on product ingredients,
   b) Strategies focusing on product structure
   c) Strategies of waste disposal optimization [5]

Ecodesign is not an unknown concept for Czech engineering designers and some manufacturing corporations. Ecodesign activities are mainly concerned with:
- substitution of dangerous material with less dangerous ones,
- implementing measures leading to waste minimization,
- reduction in raw material consumption,
- packing and transportation optimization.

### 3.3 ECODESIGN IN THE CZECH REPUBLIC

Product innovation volume in the Czech Republic, however, is unsatisfactory. On the basis of the Innovation and Development Centre investigation from 2004 it is obvious that the total investment in development and innovative technologies in companies was only 48 billion Czech crowns, which is less than 2 % of the sales in all innovating companies.

According to these investments 45 % was spent on new technologies and equipment, but only 2 % was invested in design projects.

### 4. ECO-LABELLING (ENVIRONMENTAL DECLARATION TYPE I.)

#### 4.1. CONCEPT OF ECO-LABELLING

Ecolabelling is a certification system for products and services that are friendlier to the environment than similar products and do not have such a negative impact on the environment. This system is directed by a third party who has to be independent.
Nowadays there are more than 30 ecolabelling systems and their number is increasing. National or supranational labels are assigned within those systems. Ecolabelling is regulated by ISO 14024.

The main task of ecolabelling is to:
- choose product groups whose negative impacts on the environment can be reduced,
- set a group of requirements that are to be met by the product groups, so that the product groups can be legitimately considered as environmentally friendlier. These requirements are to be disclosed in an appropriate way.
- assign the eco-labels (in the form of a licence contract) to products that meet the given requirements,
- crosscheck the compliance of features of the labelled products with the licence contract requirements. [2]

The products and services that apply for certification have to meet many requirements concerning the quality of the product (service), particular production phases, and usage of raw material, technologies and final disposal.

In contrast to the majority of preventive strategies focusing on systematic examination of manufacturing processes, ecolabelling makes use of market mechanisms outside the company. The basis of market mechanisms is supply and demand. Demand is created by consumers interested in environmental issues and choosing environmentally friendly products for their consumption.

Not only features of a finished product, but all stages of product origin are assessed, despite the fact that ecolabelling is an instrument related to a product. By means of ecolabelling it is possible to influence the usage of raw material, choice of technologies as well as disposal methods of used products.

Ecolabelling is the oldest voluntary instrument; it originated in the Seventies in the then Germany. The first eco-label was ‘Blue Angel’ and it was awarded in 1978. Nowadays ‘The Flower’ is the trademark of ecolabelling in the EU.

![Trademark of ecolabelling in the EU – ‘The Flower’](image)

### 4.2. ECOLABELLING IN THE CZECH REPUBLIC

In the Czech Republic the ecolabelling system is executed as the National Programme of Environmentally Friendly Products Labelling, respectively on the basis of the Government decree Nr. 159 from April 7, 1993. [3] The following figure shows the number of ecolabelling licences awarded in years 1994 to 2004.
Despite this, the environmentally friendly products market has so far not evolved very much in the Czech Republic. Economic return is therefore relatively low. Even though the fees the producers pay are much lower than for ecolabelling systems in other countries, the ecolabelling eco-efficiency is rather poor.

5. BENEFITS ARISING FROM ENVIRONMENTAL FRIENDLY BEHAVIOUR

Many companies are reluctant to implement environmental management because they are afraid of enhanced costs connected with environmental preservation.

One could say that the application of voluntary preventive strategies and instruments is not worth it. It is very costly to monitor energy and material flows, environmental costs and revenues. Using environmentally friendly raw material and other resources brings with it higher costs. Are there any benefits resulting from a company’s environmental approach?

Measures for environmental protection can really increase costs in the short-term. However in the long-term those measures should bring a variety of financial as well as non-financial benefits to a company. The question is what are the company’s preferences - short-term profit or fixing the market position, building reputation and long-term sustainable growth?

There are two ways of looking at the benefits arising from a company’s environmental behaviour and application of voluntary instruments. The first is from the benefit point of view— benefits can be divided into financial and non-financial benefits. Benefit origin is the other point of view. Benefits can be internal (arising in a company) or external (flowing from outside the company). The table below displays benefits arising from environmental behaviour divided according to these four criteria.
<table>
<thead>
<tr>
<th>ORIGIN POINT OF VIEW</th>
<th>EXTERNAL</th>
<th>INTERNAL</th>
</tr>
</thead>
</table>
|                      | • Lower fees and fines for polluting the environment  
|                      | • Larger market share acquisition  
|                      | • Lower production costs connected with waste reduction and higher efficiency (e.g. material and production costs savings)  
|                      | • Lower environmental damage remedy costs  
|                      | • Improved trading income as a result of lower costs  
|                      | • Waste disposal costs savings (incl. reduction of investment and expenditure for running end-of-pipe technologies)  
| FINANCIAL            |          |          |
|                      | • Decrease in environmental risk  
|                      | • Improved position of a company during negotiation with public institutions  
|                      | • Enhancement of company image  
|                      | • Simplification of EMS  
|                      | • Getting into the new markets  
|                      | • Possibility of engaging in a net of other environmentally conscious companies  
| NONFINANCIAL         |          |          |
|                      | • Lower waste production (fulfilment of legislation requirements concerning preservation and improvement of the environment)  
|                      | • Simplified waste management due to lower requirements imposed on storage areas for waste, waste transport and equipment for waste disposal  
|                      | • Improvement of working environment  
|                      | • Possible improvement of product quality  
|                      | • Including and interesting employees, possibility of getting first-rate employees  
|                      | • New technological innovation  

6 SUMMARY

Nowadays more and more emphasis is put on the protection of the environment. Companies can be voluntarily environmentally active above the ambit of the legislation. Companies have a wide range of voluntary environmental instruments at their disposal. One could say that applying voluntary preventive strategies and instruments is not worth it. There are a lot of financial as well as non-financial benefits arising from companies’ environmentally friendly behaviour. If a company wishes to be ahead of the competition it has to do more than the competition, and do what is not obligatory. However, the level of usage of these voluntary instruments is, for various reasons, unsatisfactory in the Czech Republic. Among the main barriers are poor awareness of these instruments, aversion to the new, the insufficiently developed green-products market and finally, lack of funds.

Manufacturing of a Pick-and-Place Robot with Inverse Dynamic and Robust Controllers

S. Saeed Mirian¹, S. Mohsen Safavi²

¹Islamic Azad University
Najafabad branch, Isfahan, Iran

²Isfahan University of Technology
Isfahan, Iran

ABSTRACT

In this research, designing and manufacturing of a pick-and-place robot, along with its kinematic and dynamic analysis have been introduced and surveyed. Simulations of the robot’s movement and control procedure via nonlinear robust and inverse dynamic controllers are then discussed as well as the comparison of uncertainties among them as modern control methods. The main function of this robot is coating epoxy powder on “Hawle” gate valves at temperatures up to 200° C. The results obtained in this study can greatly fulfill the need to resolve industrial problems.

1. INTRODUCTION

Pick-and-place robots are the most widely used traditional robots in industry with their functionality covering a broad range of tasks. The primitive type of these robots was first designed and assembled in 1967 for a precise casting process. The main reason to employ such mechanism at that time was hazardous environment for human operation considering toxic, gaseous emissions from the melt along and also the required high speed operational cycles and complex handling, which makes up the most prominent incentives of attention to industrial robots in the frame work of human factors engineering [1]. Since the first types of these robots were fabricated, world wide researches have been carried out on design, construction, handling control, path optimization, and their dynamic load capacity enhancement. Among such researchers, Fateh [2] has examined Fuzzy Impedance control in rapid operation of robots based on position, velocity, and force feedback of end-effect with the purpose of overcoming uncertainty induced by external disturbances, friction, inertia, and other dynamic effects. Moosavian and Homaeinejad [3] have studied applying of sliding mode control on a 2-DOF manipulator and reduction in chattering frequency that causes reduction in energy consumption. Ahmadi and Eghtesad [4] applied Image processing approaches to design and control of a catcher robot. Qurayem and Nickoubin have presented an algorithm to calculate dynamic load carrying capacity of a manipulator with optimal control through predetermined path. Wu et al [6] have studied an robust controller based on SISO nonlinear systems in order to precisely control the displacement of linear motors of a two dimensional table. Moreover Chon and Kwan [7] have investigated modern post processing methodologies for off-line robot programming within CIM system and reached to acceptable conclusions. This robot is a 3-DOF mechanism, which its primary function is loading Hawel valves of any type and size up to a specific capacity, handling, coating and finally unloading them on an index table at the end of each operation cycle. Securing the required level of stability in any kind of circumstances by using robust controller, considering the variable loading capability, minimizing energy dissipation, enabling off-line changes into the program and movement path, facilitating modifications in system operation and accuracy of the gripper trajectory, constitute the outstanding advantages of this robot. The results of this study are widely used for handling mechanisms, automation and computer aided process planning. Following sections involve the robot performance in a motion cycle based on its mechanical structure, simulating and designing of robot motion in one optimal path.

* Corresponding author: Tel.: (+98) 311-3915238; Fax: (+98) 311-3912628; E-mail: saeedmir@yahoo.com
cinematic and dynamic analysis, applying of inverse dynamic and robust control systems and introducing feedback parameters. The induced errors in each cycle are compared and discussed in the results.

2 DESIGNING AND MODELING OF ROBOT

The robot with a structure depicted in figure 1 which consists of about one-hundred mechanical, electronic and pneumatic parts, is able to start moving from a base position and coat epoxy powder on the Hawle valves with an angle of about 120° related to their initial position (θ=0°) after gripping them from an index table or conveyor belt in a cycle regarding to possible linear movements of the system (P), the hinge movement of the arm (R1) and the rotational movement of the gripper (R2), in favorable conditions. This action takes place according to figure 1 and figure 2 until the linear moving body reaches the first defined point within the length limitation of linear movement (L−0) and after the reduction of the arm angle with the horizon until it reaches to its ultimate limit in downward direction (α=36°). The angle at which the valve enters the coating tank is the angle with the best condition for absorbing the paint by the valve with the least loss (θopt=120°). After the valve is immersed in the coating tank for a definite time, the valve leaves the paint by a command, simultaneous with the re-ascension of the arm and repeats the movements as in the previous stage but in reverse direction to return the coated valve to its initial position (L~0.5, θ=0°). While the Hawle valve is leaving the coating tank, the gripper is required to accompany the rotational movement with vibration by a stepper motor in order to prevent the loss of high expenses coating materials as much as possible. While an index table or conveyer belt is employed as part feeding device, the robot is ready to perform operations on the second valve after the transfer mechanism is moved for one step.

Figure 1: Real and schematic views of the robot

Figure 2: Degrees of freedom: P (Linear Motion, L), R₁ (Arm Rotation, α) and R₂ (Gripper Rotation, θ)
Weight control of the parts and compensation of the pneumatic actuator weakness in achieving the design of every robot, the design algorithms of the movement path and robot function are the most important stages on the basis of which the required parts are designed or selected [4]. After considering different factors such as the best controlling methods for the parts of the robot to reach a complete and uniform coating, the minimization of power loss and maximum use of existing space by deleting the redundancies of degrees of freedom in such robot, studying and performing the required calculations on its initial design depicted in figure 3(a). The ultimate structure of robot was finally modified to a satisfactory final design configured in figure 3(b). The most important parameters employed in the design and simulation of robot are weight and dimensions of the Hawle valves and robot consumption power as variable quantities on the one hand, and end-effect position at intervals between movement and stopping time in one cycle as the specified quantities on the other hand. All performed through the controllers under study in this research by angle/torque feedback system, lead to successive movements of the intended parts in the specified path with desired precision in uncertainty conditions whether by sudden changes of the load or by pneumatic system weakness. The consumed power of the system which is drastically the function of time of each cycle will reach to its least amount by optimization of the movement path and quantification of time.

3 Kinematic and Dynamic Analysis

In order to facilitate the analysis of this system, the robot degrees of freedom were separated into one linear movement and two rotational movements related to one robot with two degrees of freedom and the results obtained were combined with each other. Therefore, in this section only the process of cinematic relations of one robot with two degrees of rotational freedom is discussed. In the cinematic analysis of this problem, the rotational matrices of A-1 is specified in the form of Equation 1 and the solution for finding its rotational matrices is performed by employing Denavit-Hartenberg amounts in table 1 [8, 9, 10].

In this table different quantities such as $\theta_i$ in rotational manner from $X_{i-1}$ to $X_i$ around $Z_{i-1}$, $\alpha_i$ rotation from $Z_{i-1}$ to $Z_i$ around $d_i$, $X_{i-1}$ distance from $X_{i-1}$ to $X_i$ in the direction of $a_i$ and $Z_{i-1}$ the distance from $Z_{i-1}$ to $Z_i$ in the direction of $X_{i-1}$ are defined according to figure 4. In this figure, the two-link system of robot is specified by specifying the main link and its mass center position on relative coordinates related to the center of rotation and in figure 5 the physical specifications related to the main link such as material, mass, and moment of inertia rates considered in dynamic calculations are taken into consideration [8, 9, 10].
The unknown angles of $\theta_i$ can be calculated by knowing the final position of the gripper and by employing Eqs 2 and 3 inversely. Also Eqs 4 and 5 are used in this article in order to solve the gripper instant velocity and acceleration by Jacobian Matrix (JM); so that the numerical data extracted from the following equations will be employed for the processing related to the path follow-up in the control simulation and will be pointed in next sections [10].

With regard to Eq. 6 in which $\tau$ is the moment vector, $\mathbf{M}(\mathbf{q})$ is the inertia matrix, $\mathbf{C}(\mathbf{q},\dot{\mathbf{q}}) \in \mathbb{R}^{n \times n}$ is the matrix of centrifugal force effect and $\mathbf{g}(\mathbf{q}) \in \mathbb{R}^n$ is the effect of gravity in the dynamic analysis of the robot, then it is possible to specify the torque related to drive motors. The rates of torque obtained here along with the obtained empirical rates from the feedback system are analyzed and compared which will be pointed out in next sections [8, 9, 10].

$$\tau = \mathbf{M}(\mathbf{q}) \ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) \dot{\mathbf{q}} + \mathbf{g}(\mathbf{q})$$

$$\{\ddot{\mathbf{x}}\} = \left[\mathbf{J}\mathbf{M}\right] \{\ddot{\mathbf{q}}\} + \left[\mathbf{J}\mathbf{M}\right] \{\dot{\mathbf{q}}\}$$

4 Applying Control on the System

4-1 Inverse Dynamic Control

In the control of robots, the Inverse dynamic control is one of the control methods employed in non-linear systems with optimized non-sympathetic stability. In this section vector $\mathbf{g}$, moment of inertia, $\mathbf{m}$ and $\mathbf{z}$ are first calculated and stored. With regard to the Inverse dynamic control law which is defined in equations 7 and 8 for the robot and equation 9 for the controller, $U_0$ is replaced in the first line of equation 9 and equation 10 is resulted, which can be compared with equation 7 and the general law for this control is extracted according to equation 11. [8, 9, 11]

$$\tau = \mathbf{M} \ddot{\mathbf{q}} + \mathbf{C} \dot{\mathbf{q}} + \mathbf{g}$$

$$\tau = \mathbf{M} U_0 + \mathbf{C} \dot{\mathbf{q}} + \mathbf{g}$$
With regard to the difference in the function of $\theta$, the rate changes related to each $\theta$ is inevitable, therefore, $K_p$ and $K_d$ matrices in this research with regard to the robot specifications and constants, are considered the diametric matrices with different rates on diameters. The application of such controller requires inertia matrix, Coriolis and centrifugal vectors, gravity acceleration and system damping calculations. These quantities required to be calculated in on-line manner, because in this position, the control is based on non-linear response in the present condition of the system, therefore, the mentioned calculations of the quantities are not possible before performing operations and in off-line manner. The Inverse Dynamic control laws also require that the system dynamic model parameters be recognized precisely and movement complete equations be calculated in real time. The intended model is usually recognized on the bases of incomplete knowledge present in relation with mechanical parameters and un-modeled dynamics along with a degree of indefiniteness. Also, the unknown rate of dependence of the model to the rate of end-effector load and its load carrying capacity causes not be able to define an appropriate compensation rate in the controller for it. As a result, the use of other controllers which lack such a limitation are taken into consideration. Even though this control method is able to provide an appropriate function, but compared to the moment disturbances and environmental indefinites, it enjoys high sensitivity. As a result, a robust controller can be employed for overcoming such problems. This controller, in addition to providing logical responses, enjoys reliability, strength, and appropriate stability in the presence of moment disturbances and uncertainties. [8, 9, 11]

4-2 ROBUST CONTROL

The aim in robust control is to estimate few parameters in online manner instead of estimation of large number of independent dynamic parameters of a robot. In this position the $M, \dot{C}, \dot{\bar{g}}$ terms are not available and deleted from control command. By taking equations of robust controllers, a law will be extracted according to equation 12 [12, 13]. After simplification, Eq. 13 will result in which “$w$” is replaced according to Eq. 14 and robust control equation will be obtained in the form of Eq. 15 [10, 12, 13].

\[
\tau = -K_d \dot{\sigma} + u_0 = K_d r + u_0
\]

\[
u_o = -\left(\beta^T \alpha^*\right)^2 \sigma
\]

\[
u_o = -\left(\beta^T \alpha^*\right)^2 \frac{\beta^T \alpha}{\beta^T \sigma} \sigma
\]

\[
\dot{\sigma} = -K_d \sigma
\]

\[
M \dot{\sigma} = -K_d \sigma + u_o - C \sigma - w
\]

\[
w = M (q) (\dot{q} - \dot{\bar{q}}) + V_m (\ddot{q} + \dot{\bar{q}}) + g (q)
+ F_d \ddot{q} + F_s (\dot{\bar{q}}) + \tau_d
\]

\[
M \dot{\sigma} + C \sigma + K_d \sigma = u_o - w
\]

\[
\rho \geq \|w\|
\]
In this article $\rho$ is calculated as a scalar number with the estimation of $\delta$ online according to equation 16.

$$\rho = \delta_0 + \delta_1 \|e\| + \delta_2 \|e\|^2 \geq \|w\|$$  \hspace{1cm} (16)

Figure 6: Tracking the path with considering uncertainties via

(a) Inverse Dynamic control and (b) Robust control.

5 Analyzing the results of the trend of two control methods

After simulation of the two Inverse Dynamic and Robust control methods by MATLAB software on the basis of the data obtained from the dynamic and kinematic analysis of the robot, the results of this section were studied and compared. It is assumed here that the real $q_r$ are different from $q_d$ by 0.005 radians and the speed and acceleration are different from the given data by 0.001. In cases where there is no uncertainty, the resultant results of the Robust controller with Inverse Dynamic controller are completely similar and the error is quickly biased to zero in following a desired path. In uncertainty conditions in the system, the results obtained from comparison of Robust with Inverse Dynamic are different as depicted in figure 6. As the chattering phenomenon occurs in the Inverse Dynamic method, the error value compared with robust controller is higher. This phenomenon is specified in figure 7. It shows how the problems in obtaining the required precision in tracking an optimized path against obstacles are removed by utilizing robust controllers. [12, 13] The most important cases considered here as the uncertainties in the controller, are the probable changes in weight and dimension of the parts, sudden loads, and weakness in the pneumatic actuator system.

Figure 7: The error value and the manner of chattering phenomenon
6 Feedback Systems

There are different systems and quantities which are employed in many experiments as the bases for hardware and controller feedback variables. Attention to the angle feedback by exploiting rotary encoders is a common method for this job in which the extracted data from this method in following the robot movement path within the time of one cycle is specified in figure 8. Although the basis of angle feedback is more precise comparing to the other methods such as torque feedback, the obtained instant responses which are considered as the controller inputs for evaluation of the rate of uncertainties are consistent to each other in appropriate conditions within the limited defined tolerances and only within short time limits. In conditions that load changes produce sudden disturbances resulting in great torque changes in the system, noticeable differences are observed. In this state, due to chattering phenomenon, Inverse Dynamic controller is not able to keep the required precision. On the other hand, the use of the torque method provides the possibility of proper adjusting of the frequency so that it is possible to adjust the times of activating acceleration and stoppage of the system in a way that the uncertainties resulting from inertia reaches to its least amount and its bias to zero is neglected.

7 Conclusions

In this article, after pointing to mechanical structure and function of a pick-and-place robot, simulation of robot movement in an optimized path, kinematic and dynamic analysis, we embarked on the trend of the two methods of control as Inverse Dynamic and Robust methods in following a desired path due to simulation and experiment analyses and also results obtained from the error values in each cycle were compared by means of introduced feedback systems and quantities. Consequently the use of a robust controller seems necessary since the change in mass or size of the parts displaced by the robot and other probable uncertainties should be considered.

ABSTRACT

This survey discusses the impacts of shift work towards shop floor workers’ safety and health in a manufacturing company. This study had used the survey methodology to study the shop floor workers’ perception of shift work towards their safety and health. The survey questionnaires were distributed to 200 shift workers in the production department. The survey questionnaire covered in detail the shift workers’ background, health and safety effects and personal factors towards safety and health. The survey was conducted in a company, which is practising a rotating 3-shift, 8-hour per shift system. In order to identify the most dominant factor that influence safety and health among shop floor workers, the survey results were analyzed using the descriptive and correlation technique. Based on the findings obtained from the survey, the authors had suggested the case study company to be more sensitive on the effects of shift working towards shop-floor workers’ safety and health.

1. INTRODUCTION

The term ergonomics is derived from the Greek words ergon (work) and nomos (natural laws). Ergonomics is the study of human capabilities, physical and mental limitations in relation to their work demands and fulfilling the natural laws [1]. Shift-work is broadly defined as an arrangement of working hours that uses two or more to extend the operational work hours beyond the conventional office hours [2]. Shift-workers might work in the evening, in the middle of the night, overtime or extra-long workdays. They might also work regular days at one time or another. These types of schedules (i.e. combination or rotating shifts) are commonly practice in manufacturing industry [3].

2. LITERATURE REVIEW

In today’s modern technology, it had made possible to perform many activities at any time of the day or night. Our “24-hour society” requires that important services be provided at all times [3]. Shift work is widely used in manufacturing industry for economical reasons, such as increasing capacity rate to more than 3 times, compared to the normal 8-hour shift production output. This system is required by technological requirements for continuous plant operation that need to fully utilize the available machines and tools [4].

Bernardino (1713) as quoted by Costa (1996) states that, although the benefits of rotating shift to increase productivity and decrease production cost, but on the other hand, it can present high risk to human [5]. In fact, it can have negative impacts on workers’ health and well-being, in four aspects such as: biological function disruptions, working ability, social interaction, and deterioration of health. Biological function disruptions are caused by disturbance of normal circadian rhythms of the psycho physiological functions, beginning with sleep and wake cycle. Logically, we expect the impact of multiple shift work features shall reduces workers’ productivity and results in higher accident and a mistake rate during work. Difficulties in social interactions such as maintaining the normal relationships both at family and social level, which result in negative influences on marital relationships, care of children and social contacts [6]. Barnes-Farrell et al. [7] believed that erratic shift can cause conflict of interest between work and family.

* Corresponding author: Tel.: (603)-8921 6117; Fax: (603)-8925 9659; E-mail: hjabba@eng.ukm.my
At the same time, they can also contribute to other potential risks such as: psychology condition, digestion disorder, short sleep length, and physical system such as anxiety and interference. Furthermore, in the long term, it could cause problems with respect to gastrointestinal, neurophysic, cardiovascular control and sadness [6].

3. Research Methodology

Data collection involved two main sources namely: a survey method and a case study on the design of shift work schedule. The data collection techniques used was observation method, structured interviews and analysis of document. Data analysis had used descriptive techniques to obtain the distribution for each segment. This technique was also used to identify significant factors towards health disruption, safety disruption, design of work schedule and individual element on shift working difficulty. Likert scale was used in the survey questionnaire form to measure workers’ perceptions on each question. Hayes [8] suggests the Likert scale based on five different categories, namely: (1) highly disagree, (2) disagree, (3) unsure, (4) agree, and (5) highly agree. For the purpose of this study, the authors had combined highly agree and agree and also highly disagree and disagree to two attributes, namely “agree” and “disagree” during data analysis process.

The survey questionnaires were distributed to Company X. The two main reasons for choosing Company X for the survey were due to their efficient management and human resource system. In this study, the survey questionnaires were distributed to 200 shift shop floor workers in the production department. The questionnaires were collected immediately to avoid missing questionnaire and most important, to ensure attention were given in answering the questions. The survey questionnaires distributed comprised three main sections. Section A covers the demographic information to describe the profiles of shift workers such as age, marital status and academic qualifications. The reasons to choose these criteria are inline with Rosa and Colligan [3] statement that states: age, gender, marital status, economy, individual factors and design of work schedule play important roles with respect to workers’ safety and health. Section B listed two main aspects with a number of factors or causes that are related to the objectives of the study; namely: health disruption, safety disruption. Section C had asked questions on the workers’ perception with respect to the shift system. In this study, aspects which received 60% or more points in term of agree and highly agree are considered as critical. Meanwhile, aspects which received 40% points in terms of disagree or highly disagree are considered uncritical.

4. Analysis Survey Results

4.1 Background of Company X

Company X was established on April 24th 1916 as a gold plate manufacturer in Klang Valley, Selangor, Malaysia. Later on, Company X progressed to become a manufacturer for producing sensors in automotive, aircraft and Heat Ventilation & Air Conditioning (HVAC) industries for local and international market. Company X produces four types of sensors namely; Micro-fused Gauge Sensors (MSG), Occupant Weight Sensors (OWS), Air classifications module (ACM), and Differential Pressure Sensors (DPS). The main customers of this company are Ford, Mitsubishi, Siemens and Honda. Company X employs about 1500 full-time staff, covering two systems of work schedule, normal shift and rotating shift. About 1000 shop floor workers, technicians, engineers, and others are working using the shift work system, while the rest (management division) practice normal work schedule. Company X had implemented a rotating 3 shift system that consists of 8 hours per shift, namely morning, evening and night shift.

4.2 Demographic Background

The shop floor workers comprise of various age groups: 40% less than 25 years old, 53.5% less than 46 years old, and 6.5% age above 46 years old. About two thirds of shop floor workers had married and more than 130 of them already have children. In term of monthly income, most of the shop floor workers are paid between Malaysian Ringgit (RM), RM 1001 to RM 2000. The percentage of shop floor workers’ income below RM1000 and above RM 2000 is approximately the same. The survey results shows about 77% of the shop floor workers had worked in Company X, 5 years or less. In term of academic qualification, 74% of the shop floor employees are educated up to the middle secondary school level. Furthermore, with respect to medical leave and attendance record, more than 60% of shop floor workers took medical leave and 43.5% of them were absent around 1 to 2 times per month.
4.3 HEALTH AND SAFETY FACTORS AND ITS CAUSES

There are two main aspects that could influence health and safety of shop floor workers at Company X, they are; health and safety effects. These factors are based on the previous studies on shift work that listed several elements which have influence on safety and health of shop floor workers. Under the previous four shifts system, employees at Company X work for five days, 40 hours each shift and take leave for 2 days after that, before changing to following shift. Each shift has a 40 minutes rest period. Based on an interview with the employees, the young employees like this shift system due to its potential to higher income. On the other hand, married employees are complaining with respect to the long working hours and insufficient time to rest, leisure and housework. In relation to the design of workplace, most of the employees at the shop floor are required to stand-up for 8 hours a day except for those who are working at Quality Control Department. In fact, stress and awkward posture caused by this working condition may have negative effects on their health and safety. From the survey questionnaires, the authors had listed down all the critical and uncritical aspects.

4.3.1 HEALTH EFFECTS

In the survey questionnaire, the authors had investigated fifteen issues on the health effects, which comprise of: (1) sleep deficit, (2) interrupted sleep, (3) stress, (4) fatigue, (5) depress symptoms, (6) headaches, (7) digestive disorder, (8) high blood pressure, (9) heart problem, (10) difficulty in managing daily life activities, (11) frequent fever, (12) lack of focus, (13) nutritional disorder, (14) lack of focus on family and friend, and (15) insufficient time for social activities. Results of the survey are shown in Figure 1.

![Figure 1: Health Effects among Shop Floor Employees](image)

With respect to Figure 1, cumulatively, 77% of shop floor workers had chosen “agree” to lack of focus with family and friends. In addition, 75.5% had responded “agree” on sleep deficit, 66% chosen both interrupted sleep and lack of time for social activities. As many as 65% shop floor workers reported to having difficulties in managing their daily life activities, 63% experienced fatigue, 57.5% have frequent headaches and 53% of them faced lack of focus as a result from shift work. On the other hand, of 55% shop floor workers were unsure whether working on night shifts have elevated themselves risks on developing heart problems and 48% were unsure about any perceived relationship between high blood pressure and working at night. Whereas, a few of effects are below 50%; 45.5% of shop floor workers faced depressed problem, 42% of shop floor workers faced mental and physical stress, nutritional disorder and fever; and 37% of shop floor workers experienced digestive disorder. From this research, it shows that there are six critical health disruptions found in the survey. The top two critical health disruptions showed large percentage gap from the rest; they are: 1) lack of focus with family and friends; 2) sleep deficit. Meanwhile, the other four health disruption had more than 60% responded “agree” on interrupted sleep, insufficient time for social activities, difficulty in managing their daily life and fatigue.
 Compared with people who work in normal working hours, shift workers report more interference to their family lives, especially the time available to spend with spouses and children. This fact is very important since the amount of time and quality of social interaction is related to physical and mental health. Individuals who cannot establish regular routines in their daily activities have difficulties planning for family responsibilities and coping with physical and mental fatigue as effectively as non-shift workers. This phenomenon is inline with Rosa and Colligan [3] statement, which stated that the morning shift employees on daily basis have to wake up from their sleep too early. As a result, it will cause sleep disruption and fatigue, thus reducing their quality of sleep and sleep time. In addition, they also faced problems in social interactions with their families and friends.

According to Costa [6], shift work can cause a negative effect to the human psychological condition. In fact, the human body is exposed to a continuous stress in its effort to regulate as swiftly as possible to the new working hours, while at the same time, it is being consistently frustrated by the continuous change-over. As a result of these problems, the employees will suffer anxiety, depression and digestion disorder. In the long run, they could result in gastrointestinal, neurophysic, and cardiovascular problems. In addition, a recent study by Tepas [9], found that due to the long shift hours, one must have strong physical and mental strength, especially for old employees.

In general, the survey results shown in Figure 1 are based on the short term effects due to the human body’s failure to accept and control the circadian rhythm. Approximately 50% of the surveyed shop floor workers were unsure whether they face a higher risk to heart attack and high blood pressure due to shift work. A more conclusive data could have been obtained if the shop floor workers were actually checked by a physician to determine their actual physical and mental health. One of the reasons why the shop floor workers were unsure of their actual health conditions are because they rarely undergo medical checkups, and they felt they are still young and healthy. This is reflected on the shop floor worker’s background, where more than 77.5% have been working for less than five years, and that 78.5% were less than 35 years old.

4.3.2 SAFETY EFFECTS

Figure 2 shows, six safety effects, namely: (17) lack of focus during work, (18) always make mistakes, (19) sleepiness during work, (20) fatigue, (21) involved in minor or major accident at workplace, and (22) involved in accident during traveling to work. With reference to Figure 2, cumulatively, 76.5% shop floor workers agreed that they feel sleepy during work, 58% experienced lack of focus, and 51.5% admitted that they make mistakes during working hours. On the other hand, there are three effects that registered less than 50%, namely; 46.5% experienced fatigue during work, 43.5% involved in minor or major accident at workplace, and 40.5% involved in accident during traveling to work.

Based on Figure 2, sleepiness during working time is the most critical safety disruption compared to another safety disruption. It is due to fatigue and insufficient sleep. It is related to the disturbances of circadian rhythms which can affect concentration, motivation, and reaction time, particularly at night. This combination can result in an increased risk of accident and injury. Besides, Tepas [9] also stated that instability sleep time will caused declining sleep quality and make the human employee feels sleepy especially during the afternoon. However, from this study, there is a disagreement about shift workers accident rates. It is not a very critical safety problem at this company. Only 40% of shop floor workers involved in accident while traveling and at workplace. Part of the reason is that work conditions are not always same on different shifts. For example, the amount of supervision, nature of workload and backup systems available can vary from one shift to another shift. Besides, the shop floor workers also agreed that adequate facilities and provided transportation help them a lot to avoid accident during travelling to workplace. According to Tepas [9], most accidents are caused by fatigue and they occurred from 12 mid night to 4 am in the morning. The factors that contributed to severe fatigue at this stage are insufficient rest period, sleep deficit, many physical activities, work surrounding, stress and lack of nutritional.
Section C had asked shop floor workers on their shift work schedule. This survey considers the length of rotation period, which consist of working day and rest period of at least 24 hours after each set of shift works. There are three questions, two objective questions and one subjective question. In the first question, comparison was made on average of sleep duration for the three shift systems. For the second question, it had asked on the type of comfortable shift system among the shop floor workers, which comprise of 5 working days and followed with 2 days leave, work for 4 days and take leave for 2 days after that, work for 4 days and take leave 3 days, and etc. The last question had asked about the improvement that needs to be done on their design of shift system. From the survey, most of the shop floor workers had suggested the improvement on rest period and also working conditions.

With reference to Figure 3, there are eleven items (labeled 23 to 33) that need to be considered in the design of work schedule: (23) number of consecutive work hours, (24) number of consecutive working days, (25) number of annual leave, (26) number of short breaks, (27) tired at work, (28) need for overtime, (29) need to work on public holidays, (30) frequent changes of schedule, (31) hard to do work rotation (morning, evening, night), (32) difficult to work on night shift, and (33) standing during working time.
In fact, it is very important to study the human factors which involved shop floor workers’ limitations, constraints, comforts and acceptance on job design. Figure 3 show about 81.5% shop floor workers complained that they are not comfortable with standing during working, 77% of shop floor workers said that they have insufficient rest duration, 74.5% of shop floor workers agreed that night shift is hard to track, and 68.5% of shop floor workers feels that their weekend leave is insufficient. Furthermore, 62.5% shop floor workers think that rotational shift is hard to follow, 57.5% of shop floor workers complained that there are too many working days, and 49.5% believed that their work need a lot of physical energy and they are forced to do overtime. On the other hand, about 52.5% of shop floor workers did not agree that they have to work during public holidays and 50.5% feel that work duration should not be extended.

Referring to Figure 3, standing during working time is the most critical factor at Company X. It is due to work requirements that require most of the shop floor workers to stand during work hours. In addition, more than 70% of shop floor workers agreed that short break and difficulty in working night shifts are two most critical disturbances factors at this company. There are two factors that had registered more than 60%, namely; insufficient holiday leave and difficulty in shift rotation. All the five factors are associated with the fatigue and other health disruption as discussed earlier. Tepas [10], pointed out that fatigue is related to two issues such as total time of each long shift and total of rest hours. Others stressed that hard physical work, continuous observation and insufficient rest may result in the deterioration of performance and reduce productivity among the employees.

4.5 SLEEP DURATION PER SHIFT AND SHIFT SCHEDULE

The shift work may alter the time and duration of sleep quality. The daytime sleep is seldom as deep and refreshing compared to sleeping at night. The problem is greater if the sleeping place is not a quiet, dark and comfortable. Even when disturbances are removed, a worker who returns home in the morning may still find it difficult to sleep or less refreshing. With respect to the sleep length, a reduced number of sleep hours’ is recorded for three shifts. Figure 4 shows the differences of sleep duration during night, morning and evening shift. The survey indicates that the employees experienced sleep deficit due to shift work, where 54% shop floor workers sleep in abnormal range (three to five hours a day). As a result, this problem which is known as circadian rhythm conflict will influence the employee’s productivity especially at night. Being constantly tired is a typical complaint of shift workers. In the long run, such condition may cause problems to the nervous system and in turn, increase the risk employees’ to health and safety.

![Figure 4: Sleep Duration Per Shift](image)

Optimizing the design of the shift schedule is the most effective way of reducing the health and safety problems. Satisfaction with a particular shift systems is the result of a complicated balancing act that is the best compromise for personal, psychological, social and medical concerns. Figure 5 shows the survey results on the most comfortable shift schedule as perceived by employees. Most of the shop floor workers are comfortable with working for 5 days with 2 days leave beginning the next day and work for 4 days with 3 days leave starting the next day. The percentage of both
schedule is approximately the same. From the survey data, the young employees had a tendency to choose work for 4 days because they can get extra leave. On the other hand, most of the old are employees comfortable to work for 5 days because their commitment to their families. Besides, working for 5 days need only 8 hours per day if compared to 4 days working day that need 12 hours per day. According to Tepas [9], the disadvantages of 12 hours per day are insufficient time to sleep, fatigue, and difficult to manage their daily life activities.

Figure 5: The Most Accommodating Shift Schedule Possible

5. CONCLUSIONS

Based on the survey data analysis, consideration for shift arrangements are associated with two main aspects, namely: work schedule and the behaviour of the employees. In addition, for health effects, lacks of focus with family and friends, and sleep deficit are the two major critical aspects that need to be considered by the company’s top management. Therefore, in the authors opinion the company should be conscious of the normal working period for their employees, 8 hours per day to help them plan their activity after work. This survey results is in-line with Neil [11], findings, which pointed out that the cooperation among employees and top management is needed to determine if the current design of the shift system reflect an overload or has negative influenced on their health and safety. Apart from that, sports championship and entertainment activity are others ways to bridge the relationship and promotes mental and physical fitness of the employees.

According to this survey on safety effects, 76.5% of shop floor workers are complaining that they feel sleepy during work and suggest the top management to be aware on this matter. Most of the shop floor workers agreed that by taking the stimulant or ‘pep’ drinks like coffee, cigarette and energy drinking, this sleepy feeling will go away. This behaviour will affect the health and safety of the employees in the long run. Therefore, it is very important that a shift worker involved in exercise programs to maintain an adequate level of fitness. It is also very important not to smoke, to have a good dietary habits and to participate leisure activities. From the study on design of work schedule, most employees agreed that short break and difficulty of night working shift are the two major factors which affect their health and safety condition. These factors are related to sleeping problem which faced by almost all shop floor workers. Apart from that, in term of safety, some of employees have been involved in accidents outside the workplace. To overcome this problem, the company had provided the transportation for its employees for coming and returning from work.

In this study, regardless of working time, standing posture while working can contribute to an accident. Awareness of existing work posture and practice is essential to identify changes that should be made to reduce the risk of accident. One must also adjust the work environment to meet each individual’s needs. The human body is very adaptive, and tries to accommodate itself to all situations. Poorly designed work spaces may lead to unhealthy postural adaptations. For that reason, the company should extend the break hour to one hour per shift for employees in order to avoid accidents at the workplace. For standing workers, the company can implement the work to break ratio of 30 minutes to 10 minutes, or 40 minutes to 10 minutes for each session. Providing anti-fatigue mat or chair for standing workers is an excellent example of ergonomic approach at this company. Standing on a hard surface is
uncomfortable because leg muscles become static, continuously flexed in an attempt to keep the body in an upright position. Additionally, providing adjustable worktable which corresponds to the size and employee’s height, can contribute to lessening effects of fatigue. A wide and flexible workstation design is also essential for the employees to change their position during working. By providing the foot rest, employees can transfer their weight to the feet. In addition, wrap-around support could stabilize the elbow and reduces pain caused by repetitive movements. In this day and age, manufacturing industry needs to operate 24 hours per day in order to fulfil the customers’ requirements and accomplish their expectations. Nevertheless, the survey findings show that the shift work can also present a negative impact on health, safety and well-being of workers. One explanation for this finding is that, it is well known fact that work efficiency during the night is not the same as during the day.

As a conclusion, this study was done successfully and had achieved its objectives to study on work schedule system in manufacturing industry and relate it to the health and safety of employees. It should be noted that the background among the shop floor workers differed quite substantially. Personal assessments of physical and mental well-being and personal characteristics such as gender, education level, marital status and age undoubtedly contribute to these aspects of this phenomenon. Human factors and ergonomics elements are the core elements of this study to evaluate and access the satisfaction level and restriction during shift work. Based on the findings from the survey, the authors had suggested the company to be more sensitive on the implication of shift working on shop floor workers towards their safety and health. The re-assessment of the work schedule is necessary for productivity improvement, quality, health and safety among the employees. The company also needs to consider the ergonomics design of the system and workplace surrounding, to achieve better health and safety among the employees during shift work.

7. ACKNOWLEDGEMENTS

The authors would like to thank the Ministry of Science Technology and Environment (MOSTE) Malaysia and Universiti Kebangsaan Malaysia for their support in providing the research grant for the project entitled “Establishment of Malaysian Anthropometrics Data for the Design and Development of safe and Comfortable Driver’s Seat for Road Vehicles” (Science Fund 03-01-02-SF0073).

ABSTRACT

Mismanagement of medical waste may present an environmental health hazard. Causes of mismanagement include a lack of appropriate legislation, effective control, financial constraints and lack of education, training and awareness. This is specially a concern in developing countries like Bangladesh where a large number of people are involved in the formal and informal process of medical waste management. In this paper the management of the medical waste in Dhaka, the capital city of Bangladesh, was analyzed with an aim to propose an integrated medical waste management system in the city. Data was collected from Healthcare Establishments (HCEs) such as hospitals, clinics and diagnostic centers, waste disposal operatives, official and unofficial recycling operations and scavengers. Both quantitative and qualitative data gathering techniques were used, including observation and formal structured interview through questionnaire survey and informal dialogue.

The study focused on the character of HCE, its in-house and municipal management (collection, temporary storage, transportation, treatment and final disposal options of medical waste) practice in the study area. The results indicated that the management of medical waste had not been conducted properly. Deficiencies, inconsistencies and improper processes were revealed. Malpractice was observed, among individuals involved in handling medical waste, in mid-level management, and also in the senior management level. The study revealed the need for training, capacity building programs of all employees involved in medical waste management, to promote awareness and focus on environmental and health risks of medical waste. The results obtained may be generalised to most economically developing countries where there are similar environmental problems and strict budgets.

1. INTRODUCTION

The management of medical waste is an emerging worldwide concern. In the last few decades there has been a rapid growth of medical and patient related services around the world [1]. These have increased not only use of chemicals and drugs, but also increase in the use of disposable items [2] and consequently, large amounts of medical waste are being generated on a daily basis. As medical waste contains highly toxic chemicals and pathogens [3, 4, 5, 1, 6], it is generally considered a threat to environmental health and safety. It produces unpleasant smells and infestations. Infestations may in turn contribute to the transmission of diseases [8, 1, 9]. In most developing countries there is a growing concern that the enormous amount of hazardous medical waste generated, not only results in a huge disposal costs, but also creates the potential for the spread of diseases [7], Causes of medical waste mismanagement in developing countries include a lack of appropriate legislation, effective control, financial constrains, lack of education, training and awareness; and other related social problems [8, 9, 10].

In Bangladesh, like in many other developing countries, there is little emphasis on the proper management of medical waste [11]. Most of the advanced and comprehensive medical care and treatment services are available in Bangladesh. A number of reports have indicated that medical waste in Bangladesh has suffered from mismanagement practices that deviate substantially from the standard acceptable practices suggested by World Health Organization (WHO) [11, 13, 14, 15]. Such practices may create potential public health and safety risks, particularly to the individuals who are involved in waste related livelihood, but also to the general population.
The objective of this study was to investigate the contribution of mismanagement of medical waste to environment and health risk in Dhaka city. It was intended to gather information that would contribute to the development of medical waste management plans for developing countries, which could be adapted according to circumstances and which could be harmonised with the European Union Health-care Waste Management Regulations/Directives. It is likely that this would be helpful to minimize the risks of health and safety.

2. METHODOLOGY

2.1. SAMPLING AND DATA COLLECTION

Sampling: In this study the representative sample of HCEs was selected. Both purposive and authoritative sampling system were used to select individual respondents such as scavengers, waste collectors employed by Dhaka City Corporation (DCC), waste treatment facility employees, recycling operators and their employers, and related government and Non-Governmental Organization (NGO) officials and academics. Sampling methodology and sample size determination technique has previously been described [11, 12].

Qualitative Data: Qualitative data were obtained through observation, formal structured interview and informal interview as described below;

- Physical observation
  - HCEs (hospitals, clinics and pathology centers)
  - Medical waste treatment facility,
  - Medical waste recycling operations,
  - Government departments and NGOs related with medical waste activity
- Formal Structured Interview
  - Management authority of HCEs, waste treatment facility
- Informal interview
  - Relevant government, NGO and academic personnel,
  - Recycling operations’ employers.

Quantitative Data: Quantitative data was gathered through questionnaire survey among the individuals described below;

- Administration of questionnaire on
  - Employees of the various departments in the Health Care Establishments who are
    - Working directly with the patient care
    - Transferring waste from inside bins to road site bins
    - Working for mortuary departments.
  - DCC waste collectors, employed by DCC to collect waste from road side bins and to transport it to designated dumping places
  - Operators working at official medical waste treatment centers.
  - Scavengers involved in unofficial scavenging and resale of medical waste.
  - Individuals involved in informal recycling and repacking of medical waste.

2.2. DATA COLLECTION

The research methods (including the quantitative questionnaire and the structure of the formal interview) were approved by the Ethics Committee at Teesside University.

Initially, data was collected using an observational ethnographic approach [11, 12]. In the survey phase, administration of questionnaires was carried out between December 2005 and June 2006. Selected participants were briefed about the study, confidentiality was assured and written consent obtained. The questionnaire was pretested with a sub-sample of each group of selected participants.

FSI: Formal Structured Interview; II: Informal Interview

Table 1 shows how different methodological approaches (formal structured and informal interview) were used with each group to gather data under the various headings considered appropriate for that group. Responses were obtained from a total of 233 participants. The data were recorded and analyzed by descriptive statistical method using MINITAB (version 15).

3. RESULTS AND DISCUSSION

3.1. TYPE AND LOCATION OF THE HCEs

All of the clinics and pathology centers surveyed were private, while 50% of the hospitals were public and 50% private. The only medical waste treatment centre identified in the study was found to have been jointly established by an NGO, DCC and international donor agencies. It was operated by NGO and located on the outskirts of Dhaka city.

Table 2 shows that most of the HCEs, 41 (59.42%) were located at the main residential area, while 2 (2.89%) were located in industrial areas, 13 (18.84%) were located in commercial areas and 13 (18.84%) were located in mixed use areas (residential coexisting with government and private sector commercial activities). A few of the pathology centers (4%) were located at the industrial area. This pattern of location may present significant dangers in the context of urban population health and safety.

Dhaka is a fast growing city, ranked 11th in the world by population (12.4 million) [19]. Expansion of the city is limited due to physical constraints. Commercial buildings are predominantly built and managed by the private sector, and mixed use developments, such as shopping malls and residential complexes, are popular. Most of the private HCEs are established in residential areas, or within shopping malls. Senior management and owners of the HCEs indicated, through informal interviews, that they have established their activities in residential areas to maximize convenience for their patients; as most people have no private transport, and there is no free ambulance service. HCEs, established in residential areas allow easy and timely access in an emergency. As there is a lack of legislation by the city authority, HCEs are allowed to dispose of their hazardous medical waste into general DCC waste containers intended for domestic waste. This leads to mixing of medical waste and domestic waste, resulting in all waste becoming hazardous. However, it was identified during the interview that management did not consider the health and safety issues for the residents of the risks of medical waste and some of them were not interested in discussing this issue.

### 3.2. **Type of establishments structure**

Of the surveyed HCEs, only 11 (15.94%) (including all 4 hospitals) were located in an enclosed site with more than one building while 35 (50.72) were housed in a single dedicated building, and 23 (33.33%) were located in a shared building (Table 3). All of the HCEs located in a single building or a shared in a building were privately owned. In some of those facilities examined, the space required for even basic provision for proper waste segregation, storage and disposal would significantly reduce the number of beds or tests that the facility could support and so reduce profitability. It was observed that none of the HCEs have an Effluent Treatment Plant (ETP) suitable for highly contaminated liquid waste. HCEs located in a single building discharged liquid waste directly to the municipal general sewerage system, and HCEs located on shared floors in a building discharged liquid waste into the building general sewerage. It was also found that some HCEs discharged liquid waste into adjacent lakes and rivers that were also used by local residents for washing and household purposes, as well as for agriculture. In 43 (62.31%) of HCEs liquid waste was discharged into a domestic septic tank system, and from there into the general sewerage system. The remaining 26 (37.68%) of HCEs were connected directly to the public sewage network. Wastewater was not being treated appropriately, the discharge may lead to potential contamination of drinking water supplies and/or environmental degradation.

During formal and informal interviews, respondents from management of these HCEs indicated that this too was due to lack of space, but also most of them did not have a positive attitude towards establishments of ETP. None of the HCE owners or managers was found to have considered waste management when establishing their business. Interviews with academics indicated that this was not due to the unwillingness of the architect or engineer, but due to the unwillingness of the HCE owner.

### 3.3. **In-house waste management**

In general, from top to bottom management a lack of knowledge about the magnitude of the problem was found during interviews, and in most of the HCEs, there was no particular section or person assigned responsibility for the in-house management of medical wastes. Even where an individual was found to have been assigned responsibility for monitoring and managing waste, they were invariably assigned additional responsibilities and they considered waste management to be a minor aspect of their duties.
Hazardous medical wastes, should be collected, stored and transported separately in a designed bags or containers which are resistant to puncture. [8,17, 18]. The different colored bags having different types of wastes can be stored in the same compartment or in the same room. Most of the HCEs did not use designated bags or containers for the segregation and separate storage of medical waste. It was observed that most of the HCEs were using normal bags and containers which were not sufficiently robust. Once punctured, these allow hazardous waste to spread to the environment. On the other hand, in some instances, bags or containers designated with hazard signs and colored for hazardous waste were used for domestic waste as well. Sometimes waste bags and containers were placed around the HCEs reception area, emergency area, operation theatre, research laboratory or blood bank department.

Sharps waste should be crushed before placing them in a specially designated metal box [20]. However, in Dhaka sharps were not collected as required which may lead to injuries during the collection and transportation. In India, 85% of sharp injuries are caused between usage and disposal [8]. No respondents indicated that their HCE recorded any needle stick injuries, so data were not available. However, most of the waste workers (94%) had experienced accidental injury mostly from used needles and other sharps [12]. Of these, 28% were considered serious. This is much higher than the rates observed in other countries. In Japan 67.3% of HCE staff reported accidental injuries, compared with 50% in Peru and 18% in USA [14].

Collection and transportation in the surveyed HCEs was carried out primarily by HCE recruited waste collectors with little or no training. It was observed that sometimes they used patient trolleys to carry waste. Typically, the HCE workers did not wear sufficient protective equipment during waste handling activities, increasing the potential risk of accidents and personal injury.

### 3.4. Existing Waste Storage

Most of the surveyed HCEs did not have designated temporary storage facilities, again due to lack of space. Of the conducted HCEs 17 (24.63%) were operating internal temporary storage while 9 (13.04%) HCEs were operating external storage. It was observed that neither internal nor external temporary storage facilities were designated and designed for medical waste with adequate area and quality standards. None of the HCEs had refrigeration to store infectious pathological waste, as previously recommended [2, 18]. Only 5 (7.24%) HCEs were using large containers to store the bags of infectious waste. Usually, these containers were placed by the road outside the establishments where there was heavy pedestrian and car traffic. It was observed that the lids of the containers were mostly left open, so pedestrians also dumped all kinds of waste into the open containers. External storage, found in the surveyed HCEs, was not properly designed or identified. Sometimes open space within the HCE premises were used as an external storage. Crude storage leading to access to hazardous medical waste by birds, animals, flies and rodents may spread germs from contaminated waste to the surrounding community and environment. When internal spaces were used for storage, it was often observed that medical waste was placed in a room along with office stationery or medical supplies.

Data in Table 4 shows that 7 (10.14%) of HCEs were disinfecting storage facilities. Most of the HCEs were not using disinfectant for decontamination and were not installing appropriate equipment for final disposal of hazardous waste. Radioactive waste were not stored for a long enough period to decay and safely managed.

### 3.5. Internal and External Transportation
Table 5 shows internal and external transport facilities used to carry medical waste within the HCEs and to waste dumping zone. None of the HCEs was found to be equipped with transport designated for disposal of medical waste within the premises. Therefore, waste workers transported medical waste by hand. Of the surveyed HCEs 5(7.24%) were found to be transporting medical waste from temporary storage to central or external storage area by using a hand held trolley with wheels which did not meet the regulatory requirements for safety (Table 5). Some of the trolleys had a closeable lid and some of them were without. The data obtained from the surveyed HCEs indicated that the time period for temporary storage was not followed strictly. Sometimes medical waste was stored for more than one day while the central storage period was in excess of two days.

*Locally made trolley operated manually

One NGO has established some medical waste management activity in Dhaka, primarily in the Dhanmondi area. Thus, in this area some HCEs (71%) were found to transport medical waste from the premises to the dumpsite separately and segregated as non-hazardous and hazardous through the operations of this NGO. In other areas the percentage of HCEs following these practices was much lower (10%). None of the HCEs was found to own a designated waste transportation vehicle. Consequently, the HCEs which were working with the NGO for medical waste management activity were fully dependent on the NGO transportation. While awaiting collection by NGO vehicle, the hazardous waste was stored insecurely, and sometimes for a long time, within the HCE premises. Thus scavengers were able to obtain access to the waste.

Waste from the remaining HCEs was transported by DCC waste crew to the general waste disposal site mixed with non-hazardous.

3.6 WASTE DISPOSAL AND RECYCLING

The survey results indicated that none of the HCEs were incinerating their infectious, pathological and sharps waste. Interviews with senior management and city officials suggest that this was due to a lack of incinerator and lack of interest by the city authority. An NGO had established a medical waste treatment and dumping facility. It was located close to houses and in a low lying area, connected with water bodies which may easily be contaminated by run-off and leachate containing pathogenic microbes. As previously mentioned, almost all HCEs discharged mixed domestic and medical liquid waste into sewer networks or into septic tanks.

None of the surveyed HCEs were currently operating any program to recycle general waste; such as office paper, cardboard, plastics, metal cans and selected glass. Most of the recyclable medical waste (RMW) was collected together with the general waste and disposed of into DCC bin or dumpsite along with other waste. Most of the HCE authorities were not aware about the RMW. Therefore, those RMW were sold mainly by the low class employee. Those employees have no idea about the risk to sold contaminated waste which may lead to significant threat more widely. It was observed and also found form the interview that the individuals who were involved with selling are more interested on income and easy access to get together in a large volume. Before selling the RMW they did not take any precaution measure if the waste was contaminated. It was found from the interview that waste was also sold by waste scavenger to recycle operator. None of the scavenger had any knowledge of risks from medical waste exposure. All of the recycle operators were found without any knowledge of risk from medical waste. Re-cycle operators were found to be involved with recycle activity without any training. It was observed and also found from the survey that re-cycle employers did not consider occupational health and safety for the employee.

4. TRAINING AND AWARENESS
The responsible personnel were not given adequate training, which leads to inappropriate management and insufficient implementation of the management system. Neither the HCEs nor the employees of the DCC in charge of collecting medical waste were trained. They were not aware of the importance of the appropriate handling and management of the medical waste, and consequently there were inappropriate activities observed during the collection and segregation of the waste generated from the HCEs.

Training programs on medical waste management for the medical staff (doctors, nurses and technicians) were limited. None of the HCEs offered any in-house training program. While some provided limited training for support staff through an NGO, this was the same program for all staff (senior management staff, administrative management, medical staff, waste worker, treatment facility staff). This supports the previous study of Ahmed et al. (2006) who found that 70% of HCEs did not offer any training, whereas Askarian et al. (2004) stated that training program and educational classes are instituted repeatedly for all personnel according to their job and the content of program is specifically designed in developed countries.

All of the waste workers indicated that orientation programs for new employees about medical waste management was not provided. Only 4 (5.79%) of surveyed HCEs displayed posters and some leaflets on hazards of medical waste to warn local residents of hazards, supplied by an NGO.

All of the HCEs and respondents (100%) indicated their needs and willingness to participate specialised training programs on medical waste management in future. Most of the HCEs 50 (72.46%) would prefer regular training, either quarterly or half yearly. All of the interviewed respondents (n=30) mentioned, training for senior management and authority was highly required while training programs for medical staff, waste handlers, and maintenance staffs were requested by more than 90% of the surveyed HCEs.

5. LEGISLATION

It was observed that none of the respondents were aware of legislative requirements about medical waste management. This was mostly because of the inefficient control and enforcement of the responsible authority. It was found from the survey that there was no legislation on medical waste management in Bangladesh. A set of regulations is being prepared by the Ministry of Environment and Forest, Government of Bangladesh which is still in the draft stage. However, authority could till apply to enforce for medical waste management in compliance with the Environmental ACT 1995 and Environmental Rules and Regulations 1997 of Bangladesh. It was found that the management of the medical waste in Bangladesh was supposed to be conducted according to the Environmental Rules and Regulations 1997. However, the Regulations were not applied by any of the surveyed HCEs.

6. RECOMMENDATION

The proposed efficient Medical Waste Management are given below:
- The waste should be categorised according to the WHO Directives and the European Waste Catalogue for the clear definition of hazardous medical waste and of its various categories in the Regulation.
- Location and structure of the HCE should be considered as a significant factor.
- Strict legislation of the medical waste creator regarding safe handling and disposal should be confirmed.
- Every stage of management should be documented.
- Autoclaving, sterilization, incineration must be considered before final disposal.
- If permit land filling should be considered as the final disposal methods. However, land filling would difficult in Bangladesh since it is a densely populated small country where it will be difficult to find appropriate land to fill. Therefore, waste generation reduction at source should be considered. Proper treatment and recline may minimize this problem.
- There should be provision in the legislation for the designation of courts responsible for handling any disputes may arise from the enforcement or of non-compliance with the law.
- A regular inspection system should be introduced to ensure that the enforcement of the legislation by a third party, penalties to be imposed for contravention and the inspection procedures should be clarified.

7. CONCLUSION

In this study, current medical waste management practices were investigated and evaluated in detail in Dhaka City, chosen as an example of the type of modern megacity found in developing countries. The findings suggest that there are serious problems in the safe handling and transportation of medical waste, probably arising from administrative and financial problems within HCEs, as well as the lack of awareness of the significance and the threats of the medical waste. These issues result in mixing of medical and non-hazardous waste, greatly increasing the total amount of hazardous waste. This could be addressed by promoting proper segregation through training,
clear standards and strict enforcement. These steps would also minimize the risk to those involved in handling waste, both within and outside the HCEs.

High Efficiency Cloning of Drug Resistance Genes Via Safe Vector Host Systems

Connolly S.S.¹,²* and Connolly S.N.²

¹Department of Microbial Diseases, St John’s Institute of Dermatology, Guy’s, Kings College & St Thomas’s Hospitals, University of London, London, SE1 7EH, UK; present address: ²School of Science & Technology, University of Teesside, Borough Road, Middlesbrough, TS1 3BA, UK;

ABSTRACT

Direct cloning of the genes originating from clinical isolates of coagulase negative staphylococci (CNS) conferring high level resistance to mupirocin (Mup⁴, >2000 mgL⁻¹) is described using a vector system based on the safe non-pathogen Staphylococcus carnosus. This approach eliminates the need for initial laborious subcloning steps via S.aureus and E.coli shuttle vectors. Thus, an 11.5 kb fragment of a S.epidermidis plasmid conferring Mup⁴ was cloned into a variant of the pCE10 vector and introduced into S.carnosus strains by a modified protoplast transformation procedure, with high efficiency (8x10⁸) observed. In this way, straightforward cloning into a host able to express the gene without requiring genetic manipulation in a pathogenic strain curtails the wider dissemination of drug resistance elements. The opportunity for CNS gene expression in isogenic host species is afforded by this system. Evidence for the co-existence of elements conferring high level Mup⁴ both as a plasmid and an integrative form in the S.carnosus chromosome is also presented. Conjugal transfer of the hybrid plasmid to S.epidermidis also indicates successful cloning of the mobility (tras) genes as part of the Mup⁴ plasmid.

1. Introduction

Resistance to high (>512 mgL⁻¹) levels of mupirocin (Mup), conferred by a variety of plasmids, has been described in pathogenic and coagulase negative staphylococcal (CNS) species of human origin associated with clinical isolates [1] [2] [3] while both high and low level (<256 mgL⁻¹) resistance has been attributed to chromosomal resistant determinants [4] [5]. Large plasmids in the size range 23-68.4 kb have been reported in both S.aureus and CNS from various health care settings since the early 1990’s where the resistance predated the application of Mup [6]. Characterisation of these plasmids has demonstrated their different restriction profiles and ability to transfer to pathogenic strains by conjugation, particularly on the surface of skin.

The mupirocin resistance (Mup⁴) gene has previously been cloned as a 13.4 kb HindIII fragment of a S.aureus plasmid via a S.aureus-E.coli shuttle vector [7]. The present study involves an alternative strategy of direct cloning of the Mup⁴ gene from S.epidermidis via a 2.15 kb truncated S.carnosus vector based on pCE10 through modification of a protoplast transformation procedure with high efficiency. Thus although S.aureus and E.coli have been routinely employed as hosts, S.carnosus serves as a more amenable, non-hazardous and isogenic cloning and gene expression system due to its ease of transformation and non-pathogenic nature. The cloned Mup⁴ gene is stably maintained as part of a conjugative plasmid and also as an integral part of the chromosomal DNA in S.carnosus conferring high and low level resistance to Mup, respectively.

2. MATERIALS AND METHODS

The Mup<sup>R</sup> plasmid was isolated from a clinical *S.epidermidis* strain, SCTD196, which also carried a penicillin resistance element, Pn<sup>R</sup>. Pn<sup>R</sup> was cured by sub-culturing SCTD196 and incubating at 40 °C. The characterisation of the Mup<sup>R</sup> plasmids from SCTD196 involved conjugative transfer of a 34 kb plasmid to a plasmid free strain, NCTC8325, which was chromosomally resistant to tetracycline. Serial conjugative transfer of the 34 kb replicon rendered various recipients resistant to Mup at a high level (>2000 mg L<sup>-1</sup>). Curing experiments involved culturing of SCTD196 and the Mup resistant recipient NCTC8325 at 40 °C in the absence of the respective antibiotics. Mup<sup>R</sup> plasmids were digested with *Eco*<sub>R</sub>I and *Hin*<sub>III</sub> (Sigma) according to the manufacturer’s instructions. Further characterisation of the *S.carnosus* Mup<sup>R</sup> clones involved hybridisation of the *Eco*<sub>R</sub>I digested Mup<sup>R</sup> plasmids with a 4 kb as well as a 13.4 kb labeled Mup<sup>R</sup> DNA probe [1]. Bacterial strains and plasmids are shown in Table 1.

Mup, mupirocin; Pn, penicillin; Cm, chloramphenicol; Asa, arsenate; Asi, arsenite; Sb, antimony; Em, erythromycin; Tc, tetracycline

An 11.5 kb *HindIII* fragment from the plasmid SCTD196 was inserted into a *S. carnosus* host strain via a modified 2.15 kb pCE10V plasmid. The same insert fragment was also cloned onto a 5.9 kb *S.carnosus* vector pCA43. Hybrid plasmids were introduced into *S.carnosus*, TM300, by a modification of the previously reported method of protoplast transformation using plasmid DNA concentrations in the range 250-2500 mg L<sup>-1</sup> [7]. The protoplast suspension was incubated at 26-28 °C for 2 min with the DNA solution preheated to the same temperature prior to its addition. The mixture was cooled to room temperature and centrifuged at 7000 rpm for 25 min. Protoplast dilutions were inoculated on DM3 regeneration medium and incubated at 37 °C for 5 hours before the addition of 3 mL of softagar containing appropriate antibiotics. Plates were incubated for 3-4 days. Transformants were selected on Mup and erythromycin, Em, solid media, and confirmed according to restriction analysis and hybridisation to a Mup<sup>R</sup> DNA probe.

Plasmid DNA was isolated according to alkaline lysis with the addition of 5.2 mg L<sup>-1</sup> lysostaphin (Sigma); purification was effected according to a standard phenol-chloroform method [8]. Electrophoresis was conducted on 0.8-1.2% agarose gels using Tris-borate-EDTA (Sigma). T4 ligase, DNA labeling and detection kits, as well as other reagents were obtained from Sigma. Other strains were routinely cultivated on Oxoid blood agar base containing Cm, 15 mg L<sup>-1</sup>; Em, 15 mg L<sup>-1</sup>; and Mup, 100-200 mg L<sup>-1</sup>.

3. RESULTS

Acquisition of the 34 kb plasmid by the recipient strains through conjugation and protoplast transformation conferred high level Mup<sup>R</sup>. The resistance was stably maintained and serially transferable to new *S.aureus* strains by conjugation at the rate of 2 x 10<sup>8</sup> to 3 x 10<sup>7</sup>. Loss of the plasmid under curing conditions rendered the strains sensitive to Mup. The efficiency of transformation of *S.carnosus* in molecular cloning of the Mup<sup>R</sup> gene and protoplast transformation was 4.8 x 10<sup>5</sup> to 8 x 10<sup>4</sup> for concentrations of hybrid DNA up to 500 mg L<sup>-1</sup>. Significantly higher efficiencies of transformation in the order of 2 x 10<sup>5</sup> to 8 x 10<sup>5</sup> were obtained for DNA concentrations of between 1000-2500 mg L<sup>-1</sup>. Characterisation of the plasmids using *HindIII* and *Eco*<sub>R</sub>I demonstrated the presence of the same fragments from the Mup<sup>R</sup> plasmid in both the clinical strain and the transconjugants; see Table 2 for the restriction profiles of the plasmids used in cloning.
while the strains remained resistant to 5.00 mgL\(^{-1}\). Curing of the Mup resistant Staphylococcus strains was achieved by treatment with a linearised plasmid (pSSC40) which was used to transform the recipient strain. The transconjugants and the clinical strain hybridised to the Mup\(^R\) probes confirming the presence of the Mup\(^R\) gene in all resistant strains. The hybrid plasmid pSSC40 recombinant generated through cloning into Staphylococcus carnosus was isolated from clones of Staphylococcus carnosus and cleaved with HindIII resulting in fragments of 11.5 and 2.15 kb. These were separated by gel electrophoresis and transferred to a nylon membrane. The 11.5 kb HindIII fragment of the Mup\(^R\) plasmid from Staphylococcus carnosus clones was hybridised to labeled 13.4 kb and 4 kb Mup\(^R\) gene probes, thus ascertaining the presence of the Mup\(^R\) gene in Staphylococcus carnosus clones. These probes were also used to detect homologous sequences in the plasmids of transconjugants and the clinical strain. The 11.5 kb fragment from the transconjugants and the clinical strain hybridised to the Mup probes confirming the presence of the Mup\(^R\) gene in all resistant strains.

Curing of the Mup resistant Staphylococcus carnosus clones led to the complete loss of the extrachromosomal 34 kb plasmid, while the strains remained resistant to 500 mgL\(^{-1}\) of the antibiotic. A chromosomal DNA fragment of 10 kb in Mup resistant Staphylococcus carnosus clones hybridised to the Mup\(^R\) probe indicating the presence of a copy of the Mup\(^R\) gene within the chromosome. The chromosomal Mup\(^R\) determinant was stably maintained under curing conditions and was not transferable by transconjugation.

*a* pSSC40 recombinant generated through cloning into *S. carnosus*

The hybrid plasmid pSSC40 was isolated from clones of *S. carnosus* and cleaved with HindIII resulting in fragments of 11.5 and 2.15 kb. These were separated by gel electrophoresis and transferred to a nylon membrane. The 11.5 kb HindIII fragment of the Mup\(^R\) plasmid from *S. carnosus* clones was hybridised to labeled 13.4 kb and 4 kb Mup\(^R\) gene probes, thus ascertaining the presence of the Mup\(^R\) gene in *S. carnosus* clones. These probes were also used to detect homologous sequences in the plasmids of transconjugants and the clinical strain. The 11.5 kb fragment from the transconjugants and the clinical strain hybridised to the Mup probes confirming the presence of the Mup\(^R\) gene in all resistant strains.

Curing of the Mup resistant *S. carnosus* clones led to the complete loss of the extrachromosomal 34 kb plasmid, while the strains remained resistant to 500 mgL\(^{-1}\) of the antibiotic. A chromosomal DNA fragment of 10 kb in Mup resistant *S. carnosus* clones hybridised to the Mup\(^R\) probe indicating the presence of a copy of the Mup\(^R\) gene within the chromosome. The chromosomal Mup\(^R\) determinant was stably maintained under curing conditions and was not transferable by transconjugation.

### 4. DISCUSSION

Molecular cloning and the expression of staphylococcal genes has been achieved via *S. aureus* and *E. coli* plasmids as shuttle vectors for the transformation of *S. carnosus* protoplasts [7] [9]. Other approaches, including electroporation for the insertion of exogenous DNA into cells and transcutaneous electrical nerve stimulation for horizontal gene transfer from CNS, have also been used with various frequencies of transformation involving *S. aureus* as a recipient [10] [11] [12] [13]. The limitations presented by handling hazardous pathogenic strains, including *S. aureus*, and the non-isogenic character of both *S. aureus* and *E. coli* have led to the promotion of *S. carnosus* as the preferred host system for expressing staphylococcal genes. The major advantage of *S. carnosus* is that it provides a safe host for gene expression due to its non-pathogenic nature. Recognition of the inert properties of *S. carnosus* and the non-isogenic character of both *S. aureus* and *E. coli* have led to the promotion of *S. carnosus* as the preferred host system for expressing staphylococcal genes. The major advantage of *S. carnosus* is that it provides a safe host for gene expression due to its non-pathogenic nature. Recognition of the inert properties of *S. carnosus* and the non-isogenic character of both *S. aureus* and *E. coli* have led to the promotion of *S. carnosus* as the preferred host system for expressing staphylococcal genes.

The introduction of hybrid DNA into *S. carnosus* protoplasts has generally relied on small concentrations of transforming open-circular DNA of low molecular weight resulting in low efficiency transformation [15] [7]. Significantly improved efficiency of transformation of the order of 8x10\(^9\) has been achieved by application of DNA at higher concentrations (1000-2500 mgL\(^{-1}\)). Other modifications include preheating the DNA suspension to 26-28°C before its addition to the protoplast suspension maintained at the same temperature; this is in contrast to previous reports of protoplast transformation and electroporation [15] [16] [7] [14].

The cloned Mup\(^R\) gene is stably maintained in *S. carnosus* as a 13.65 kb plasmid as well as an integral element within the chromosomal DNA. High level Mup\(^R\) (>2000 mgL\(^{-1}\)) is associated with the gene located on the plasmid, whereas resistance at lower levels (<500 mgL\(^{-1}\)) is attributed to chromosomal determinants. Curing and conjugal transfer experiments demonstrate that the 13.65 kb plasmid encodes Mup\(^R\) and carries the essential elements for its own mobilisation. High level Mup resistance was lost during curing with concomitant loss of the 13.65 kb element, while the *S. carnosus* strains remained resistant to lower levels of Mup. This suggests the presence of a stable chromosomal location for the resistance genes which was further confirmed by hybridisation of the EcoRI digests of chromosomal DNA with a Mup\(^R\) probe. Chromosomally resistant *S. carnosus* strains which were cured of their plasmid (pSSC40) did not transfer Mup resistance through conjugation with *S. epidermidis* and *S. aureus*, in contrast to *S. carnosus* strains which participated in serial transconjugation.
The presence of chromosomal determinants encoding both low and high level Mup resistance in *S. aureus* has been reported [17] [5], however, high level resistance has been mainly attributed to the presence of various conjugative plasmids in *S. aureus* and CNS [1] [18] [4]. In contrast, the present study demonstrates that the Mup<sup>R</sup> element is maintained in *S. carnosus* as both a plasmid and a chromosomal determinant. The protoplast transformation procedure described here serves as a versatile and efficient system for the cloning and expression of staphylococcal genes within an isogenic, apathogenic host.

Introducing a lean recruitment framework for manufacturing

Paul M Gibbons
EngD Centre in Systems, University of Bristol, Bristol, BS8 1TH, UK

ABSTRACT

This paper introduces a new approach challenging the current paradigm for the recruitment processes employed by manufacturing organizations. Typically current recruitment methods focus on a convergent process through the short listing of candidates validated against the submission of a curriculum vitae or job application form before assessment against a standard company interview template. Hiring managers work closely with their human resources subject matter experts looking for the most effective method of assessing candidate suitability to perform to the job specification requirements balanced against their own constraints such as time and availability. Problems with this type of recruitment process can lead to a subjective assessment of the candidate’s suitability to match the real requirements of the hiring manager which are only identified once the candidate has been employed. The new recruitment framework draws from two disparate theoretical frameworks homogenizing them into a new and holistic recruitment process. Drawing from the lean production framework a focus on the value adding elements in the eyes of the customer – in this case the hiring manager – identifies waste in the current recruitment process. Similarities identified in a new product introduction, total design conceptual framework are assimilated into the new process transforming the product design specification tool into a position profile specification outlining the hiring manager’s requirements. A future state map of the hiring manager’s requirement is realized by combining the position profile with a Pugh matrix tool identifying potential candidate strengths, weaknesses and similarities to the role requirements. As with the total design framework, where the wrong choice of concept can rarely be recouped by brilliant detailed design work; the wrong choice of candidate at the recruitment stage cannot necessarily be recouped by brilliant personnel management skills when the selected candidate is employed. The lean recruitment framework is introduced as an objective recruitment framework focusing on the value adding steps to ensuring the right candidate is employed matched to the realistic requirements of the hiring manager.

1. INTRODUCTION

Typically, recruitment processes focus around the short listing of candidates validating suitability against the submission of a curriculum vitae or job application form before further validation against a standard company interview template through a multiple interview process. Divergent information gathered on individual candidate suitability is compiled in parallel to a convergent decision making process identifying the most suitable candidate overall. Hiring managers work closely with their human resources subject matter experts looking for the most effective method of assessing candidate suitability to perform to the job specification requirements balanced against their own constraints such as time and availability. Observed problems with this type of recruitment process can lead to the subjective assessment of a candidate’s suitability to match the real requirements of the hiring manager which are only identified once the candidate has been employed.

This paper argues a more holistic approach - taking into account the manufacturing strategy whilst encompassing a focus on the functional requirements of the role - will deliver a lean and more effective recruitment process. Adopting an action research approach [1], as have other lean researchers [2-8], the framework development is embedded within the researching organisation. Testing the lean recruitment framework in parallel to the extant recruitment process, the Pugh concept matrix [9, 10] is introduced as a useful and transferable tool. Developed from its origins as an engineering concept design review tool, the Pugh concept matrix is further enhanced into an iterative decision making tool for identifying candidate strengths, weaknesses and similarities against a datum point of individual position profile criteria.

Outputs of the research include a proposed lean recruitment framework introducing a data based candidate selection process focusing on the value adding elements through the recruitment process.
2. LEAN PRODUCTION

Reference [11] are responsible for the seminal work introducing the lean production concept as it is know today suggesting a focus on waste elimination of individual processes at what could be considered the micro level of processes employed within a wider operation. The conceptual development was based on the findings from a 5-year international motor vehicle project (IMVP) [12] based at the Massachusetts Institute of Technology (MIT). Creating mechanisms for industry-government-university interactions at an international level, the project team set six criteria for which its success would depend on: thoroughness; expertise; a global outlook; independence; industry access; and continuous feedback. To achieve the criteria, specialists from the automotive industry were sourced from around the world to carry out case study investigations within the global automotive industry. A key finding from the study suggested the lean production concept combines the best elements of craft production with those of mass production offering a pluralist approach which focuses on delivering:

“...reductions in costs per unit and dramatically improving quality while at the same time providing an ever wider range of products and ever more challenging work”.

Overall, the study revealed the existence of a 2:1 productivity difference between car assembly plants in Japan and those in the West. These findings lead to extensive industry soul-searching [13] which resulted in further benchmarking studies confirming the lean production project revelations [14-17].

In 1994 the tangential concept of a lean enterprise [5] was introduced as a development of lean production taking a broader perspective of the extant relationships between disparate processes within the overall system of manufacture; at what could be considered a more macro level of the overall operation. The ideas behind the lean enterprise were further complemented by a set of principles presented as lean thinking [6, 18] summarised as the 5 steps to becoming lean:

1. Specify value
2. Identify the value stream
3. Make the value creating steps flow
4. Promote a “pull” culture
5. Pursue perfection

Concurrent with the fundamental conceptual work [11] was the dissemination of the lean concept to other areas of operations management research. This research culminated in the lean supply [19, 20] and lean logistics [21] concepts. Other simultaneous and tangential work led to the development of new tools to enhance the original concepts including: seven value stream mapping tools, [2, 3]; value stream mapping [22] & big picture mapping [23]. Typically value stream mapping has been used as a static analysis tool quantify the 7 wastes of lean [24] defined as:

1. Overproduction
2. Waiting
3. Transport
4. Inappropriate processing
5. Unnecessary inventory
6. Unnecessary motion
7. Defects

The most recent phase in the evolution of lean has seen the introduction of the lean consumption concept [7, 8] which is described as “a necessary and inevitable complement to lean production and is about ... providing the full value consumers desire from their goods and service, with the greatest efficiency and least pain. Similarly to other dimensions of the lean concept [19-21] the principles correspond closely with the 5 steps to becoming lean [6, 18]. This more holistic approach encompasses new ideas and in particular is interested in supplying what the end customer wants, where they want it, when they want it and without wasting their time at any time; an end customer satisfaction focused approach to the lean concept.
3. PUGH MATRIX CONCEPT

Reference [9] is responsible for the seminal work introducing the concept of total design, a systematic activity focused on satisfying the needs of the customer through a design process encompassing product, process, people and organization attributes. Reference [9, 10] developed tools focused on the product attribute development arguing this is the most important element of total design as businesses cannot exist without products. Developing the framework further, product development in the total design process is based around the needs of the customer articulated through a product design specification (PDS). The PDS is used as a datum point through the design process placing a boundary around potential design concepts matched to the customer requirements. Critical to the successful development of a new product design is the ability to generate solutions to the design problem and then evaluate these solutions selecting the one which is best suited to the PDS. Reference [9] argues in practice, the wrong choice of concept can rarely be recouped by brilliant detail design. Facilitating the design decision process a comparison matrix is introduced as a useful evaluation tool for comparing different concepts against individual design criteria identified in the PDS.

Figure 1 presents the Pugh concept evaluation matrix model [25] as introduced in the total design process [9]. Operationalising the matrix, each design concept is compared to a pre-defined datum point of design criteria (as defined in the PDS). Decisions are then made by the design team as to whether the individual concept elements are the same as the datum point (indicated by an ‘S’), better than the datum point (indicated by a ‘+’), or finally worse than the datum point (indicated by a ‘-’). Once the matrix has been fully populated a summary table at the bottom of the matrix shows the individual concept’s ability to match the requirement as well as the strengths and weaknesses in the concept design.

Figure 1: Pugh concept matrix

Reference [9] suggests key outputs of the evaluation matrix include:
- A greater insight into the requirements of the specification
- A greater understanding of the design problems
- A greater understanding of the potential solutions
- A knowledge of the reasons why one concept is stronger or weaker than another.

4. RECRUITMENT PROCESS: CURRENT STATE MAP

The key principle supporting the lean conceptual framework has been identified as a need to understand what is value adding from the customer’s perspective [6, 18] and any subsequent non-value adding activities are classified as waste and can be eliminated [24]. For the recruitment process the customer would typically be the hiring manager
who will usually look for support from the human resource subject matter experts taking reference to company recruitment policies and procedures. Therefore, key to the identification of a lean recruitment process is an understanding of what is value adding in the recruitment process for the hiring manager and for the business overall. Once the value adding element is understood -using the value stream mapping approach from the lean conceptual framework- a current state map can be completed as a platform to build a future state map of the required process which can be achieved using staged plans known as loops. The use of staged plans is sometimes necessary as in some cases the realization of a future state map in one big leap is not always possible and therefore the ideal state map can be used as an end goal pseudo objective utilizing future state maps as incremental leaps.

Figure 2 presents an input-process-output model of a typical recruitment process in this case identifying the current state of the hiring manager’s value stream. Key inputs focus on the business strategy and needs giving a requirement to source a suitable candidate through the recruitment process culminating in the final selection and subsequent hiring. The value adding elements of the identified recruitment inputs-process-outputs would focus on the key outputs including the selection of a suitable candidate to match the requirements of the hiring manager and the supporting documentation compiled during the recruitment process which could be used by the hiring manager to plan any personal development required for the recruited candidate.

Reviewing the key inputs to the identified process there is an overlap of information relating to the documentation prepared by the hiring manager including job description/position profile, internal/external job advert and interview template. Matched to this is the submission by potential candidates of completed job application forms, CVs or both. Through the recruitment process, reference is made to the candidate's job application form and/or CV and further data is collected during the interview phase as to the candidates’ suitability to match the requirements of the hiring manager using the standard company interview template.

5. RECRUITMENT PROCESS: FUTURE STATE MAP & THE LEAN RECRUITMENT PROCESS

In the eyes of the customer -in this case the hiring manager- the value adding element of the recruitment process has been defined as the final selection of a suitable candidate matched to the real requirements of the business realized through the deployed manufacturing strategy. The current state map of the recruitment process has identified process waste extant in the form of a duplication of customer owned reference documentation, multiple comparison documentation submitted by the potential candidate and added to through the short listing and interview phases by the customer and finally a lack of focus through the selection process on the real requirements of the hiring manager resulting in a subjective decision making process based on divergent and disparate data.

The future state map should therefore look to focus on the requirements of the hiring manager using these requirements as a central datum point during the recruitment process. Subsequently, any reference material and investigative techniques should focus on the comparison of the candidates suitability matched to the requirements of the hiring manager as defined in the position profile/job description owned by the hiring manager. Reference to this documentation through the recruitment process will ensure the final selection is based on the specific requirements of the hiring manager ensuring the selected candidate will fulfill their own as well as the business expectations.
Operationalising the future state map, key inputs to the recruitment process should focus on the preparation of a position profile by the hiring manager matched to their manufacturing strategy. This document can then be used to create an internal/external vacancy advert before being used throughout the recruitment process as a central datum point to compare candidate suitability. Also important is to ensure candidate applications are made using a standard application form therefore collecting data which is easily transferable in comparison to the position profile. This would be especially useful at the short listing element of the recruitment process where the hiring manager will have many applicants to consider matched to their own time constraints.

Revisiting the total design conceptual framework focusing on the product design specification (PDS) [9, 10] and the Pugh concept comparison matrix [25], there is opportunity to adapt and transfer this approach to the recruitment process forming a foundation for the creation of a lean recruitment conceptual framework and more importantly a method of realizing the future state map requirements. Developing the lean recruitment conceptual framework, the PDS in the design phase can be used to create a datum point of key criteria to the overall requirements of the designer. Similarly, the position profile suggested in the future state map can be populated with key criteria to the overall requirements of the hiring manager. Critical to the lean recruitment process at this stage is the capture of realistic requirements of the hiring manager as specific criteria in the position profile, as this will be the datum point for candidate comparison through the recruitment process. Also important is the matching of the position profile criteria to the manufacturing strategy ensuring alignment to both business and departmental objectives. During the candidate selection phase the hiring manager can compare individual candidates (the concept designs) to the requirements detailed in the position profile (the PDS).

The second element of the lean recruitment conceptual framework is the introduction of an objective decision making process when comparing candidate suitability. The framework argues the use of the Pugh matrix tool allows for the comparison of individual candidates matched to a datum point of key criteria illustrated within the position profile. Figure 3 presents a conceptual template of the lean recruitment Pugh matrix using possible criteria examples typically found in position profiles which can be added to as defined in the position profile. The matrix is populated by comparing potential candidates to an antecedent set of functionally required datum points. Each candidate is compared against the individual position profile criteria datum point to see if they are better than the requirement (marked as a plus sign '+' and seen as a potential strength), or the same as the requirement (marked as an 'S' and seen as matching the requirement exactly) or finally, whether they are worse than the requirement (marked as a minus sign '-' and seen as a potential weakness). At the short listing stage, rather than complete the whole matrix for each potential candidate, the hiring manager can focus on comparing candidate suitability against a sample of key criteria. As the number of potential candidates is reduced through the recruitment process, more of the position profile criteria can be incorporated into the Pugh matrix facilitating convergent decision making through controlled divergent data collection.

Once the matrix is fully populated the summary of strengths, weaknesses and similarities is tabulated to show the potential candidates’ identified strengths, weaknesses and similarities to the overall requirement. The matrix can also be developed further by weighting significant criteria as well as adding other important selection criteria not detailed in the position profile such as candidate availability if the requirement is urgent. Once the matrix is fully populated the final stage of the comparison process is to rank the potential candidates in order of suitability. At this point potential candidate weaknesses can be noted for further investigation at the next stage of the recruitment process or, if the candidate is selected for the role, the weaknesses can be carried over to their personal development plan as training requirements. Also at this point, the potential candidate strengths can be noted for further investigation at the next stage of the recruitment process. If the potential candidate has scored very highly this may indicate they are over qualified/experienced for the role and therefore may not be suitable. However, the potential strengths identified may be useful for developing other employees and therefore the hiring manager should incorporate this into the decision making process.

As part of the recruitment process the Pugh recruitment matrix decision criteria is populated at the time of the hiring manager developing a position profile and is then updated throughout the recruitment process from short listing through to 1st interview, 2nd interview and hiring. During the recruitment process the hiring manager accumulates a portfolio of candidate suitability summarized in the lean recruitment Pugh matrix. For the candidates not selected their portfolio can be archived for future reference if required and the selected candidate’s portfolio can be carried over to their personnel file and to the hiring manager’s departmental skills matrix.

In summary, the future state map and lean recruitment framework eliminate the extant duplication of documentation by using the position profile (PDS) as a standard document through the initiation, advertising, selection and post hiring phases of the recruitment process in parallel to using a Pugh recruitment matrix to control the convergent candidate selection in a balanced divergent candidate data collection process.
6. SUMMARY & FINDINGS

The lean recruitment conceptual framework was developed and tested using an action research approach [1] using four sequential pilot studies combining case study research [26] with an action research process of planning, observing and reflecting [27] summarized as taking an action case research design [28]. Reflecting on the usefulness of the lean recruitment framework the benefits are very similar to those identified within the total design approach to product development [9, 10]:

- **A greater insight into the requirements of the specification (in this case the position profile).** Through the recruitment process the hiring manager gets the opportunity to question why the requirement is important to the position profile and overall manufacturing strategy. Taking an iterative approach, the requirement criteria can be changed to ensure alignment with departmental objectives through the convergent and controlled divergent lean recruitment process.

- **A greater understanding of the design problems.** Through the selection process the hiring manager gains an understanding of how realistic the requirement is in comparison to candidate availability. This could mean there is a skills shortage in that particular field of expertise or that the hiring manager has set an unachievable requirement. In summary, the hiring manager will gain an understanding of candidate availability to best match the requirement.

- **A greater understanding of the potential solutions.** Linking to the understanding of design problems the hiring manager -through the Pugh lean recruitment matrix summary- gets an understanding of the possible candidates who could fulfill the roll most adequately. In particular reviewing any potential weaknesses that would require further development or any candidate strengths that could be used in the development of other personnel.

- **A knowledge of the reasons why one concept is stronger or weaker than another.** Potential candidate suitability, strengths and weaknesses are investigated through a controlled divergent process in parallel to validation through the interview phase converging at the final selection decision stage. Through the lean recruitment process, each candidate is compared against the individual position profile criteria.
datum point to see if they are better than the requirement (marked as a plus sign ‘+’ and seen as a potential strength), or the same as the requirement (marked as an ‘S’ and seen as matching the requirement exactly) or finally, whether they are worse than the requirement (marked as a minus sign ‘-’ and seen as a potential weakness). Once the final lean recruitment matrix is fully populated the summary of strengths, weaknesses and similarities is tabulated to show the overall candidates’ potential to meet the requirement. The summary table can also be ranked to show order of candidate suitability and key criteria can be weighted to ensure the candidate assessment is correctly balanced to the requirements.

In summary the lean recruitment framework eliminates the duplication of documentation, gives ownership of the recruitment process to the hiring manager and provides a convergent/controlled divergent structured approach focusing on the realistic requirements of the hiring manager through the recruitment process.

7. CONCLUSIONS

The main benefit of the lean recruitment process is the shift in emphasis to focus on the value adding elements of the recruitment process in parallel to placing more ownership with the hiring manager. Through the recruitment process, the framework provides a useful and correctly balanced convergent divergent decision making approach for non-HR specialists to use giving ownership of the selection process through comparison of their realistic requirements as defined in the position profile and analysed in a lean recruitment Pugh matrix. As with the total design framework, where the wrong choice of concept can rarely be recouped by brilliant detailed design work, the wrong choice of candidate at the recruitment stage cannot necessarily be recouped by brilliant personnel management skills when the selected candidate is employed. The lean recruitment framework is introduced as an objective recruitment framework focusing on the value adding steps to ensuring the right candidate is employed matched to the realistic requirements of the hiring manager.

Future research should look to further develop the lean recruitment process perhaps documenting the process into an easily transferable format for generic use in the recruitment process at a wider level covering other functional requirements of a business.

Abstract

The world is right now in the middle of a radical demographic transition. On the first hand the population growth is slowing down. On the other hand the age structure of world’s population is changing, with the share of younger people dropping down and that of elderly people increasing. So in most Western industry nations we have to focus a significant aging of population and therewith of human resources in firms from now to the year 2020 in a first and to the year 2050 in a second step. Cause of their psychological and physical characteristics, elderly employees underlie a different design of working systems and working conditions. In this regard it seems to be clear that firms have to challenge this changing structure of their most valuable resource to stay competitive in future economic environments.

For this attend the presented paper contributes possible managerial implications regarding the design of working systems based on the demographic change of human resources in firms. To give this objective a detailed analysis of the data of demographic change in Western industry nations, USA, Japan, Germany, and its firms are given. Related to the data analysis and the connected older growing staff in firm’s costs of this evolution are deduced. Thereto different theoretical aspects will be connected to the analysis of data. Based on these considerations basic implications for managing the demographic change are stated. Next to the central design of working systems, three other fields of related interests health, education, and culture are mentioned. Finally new illuminating aspects of future researches and developments are shown in this research context.

1. Introduction

“The world is in the midst of a major demographic transition. Not only is population growth slowing, but the age structure of the population is changing, with the share of the young falling and that of the elderly rising”, so the “International Monetary Fund”[1]. Especially for the economies in Western nations the changes are dramatic. The development in these nations will bring a significant aging of population and so to the human resources for firms from now on to the year 2020 at first and then to 2050. So Bloom and Canning from the Harvard Institute for Global Health state that connected with the prognosis of increase in global population is a complex dynamic setting of age structure, which surrounds a almost quadrupling of 60 years of age population and over by the year 2050 [2]. In this context it seems to be clear that Western industry nations and their economies as well as their profit oriented firms have to challenge this structural changing of the most valuable human resources to stay competitive in the next decades in a globalised world. Therefore demographic conditions are strongly affected by economic and social realities and institutions on the one hand, but on the other hand those realities and institutions are substantially determined contrary. This interdependency describes the underlying reflections like the two sides of one coin [3]. For the underlying research it is necessary to take a closer look by a more detailed analysis of data in combination with relevant theoretical aspects of costs. Furthermore some basic implications regarding the design of working systems, health, education, and culture are focused. The analyzed data mainly concerns the three

* Corresponding author: Tel.: (0049) 561-8043506; Fax: (0049) 561-8047029; E-mail: marion@weissenberger-eibl.de
Western industry nations USA, Japan, and Germany which are characterized by similar age structures. For some analysis the situation is focused on German data.

2. THE DEMOGRAPHIC CHANGE AND ITS COSTS IN WESTERN INDUSTRY NATIONS - THE CASE OF USA, JAPAN, AND GERMANY

The triad of USA, Japan, and Germany builds the core of analysis in the underlying research paper for two significant attributes of Western industry nations. The first attribute is that their economies are the leading head of the “Organisation for Economic Co-operation and Development” (OECD) and build therefore the most influential industrial areas. The three countries USA, Japan, and Germany are responsible for more than 50% of the contribution benefits of OECD. More detailed, the contribution in 2007 of USA is 24.975%, of Japan it sums up to 16.656%, and of Germany runs 9.265% [4]. According to this fact the called three nations realize the three highest gross domestic products in the world [5]. The second attribute concerns the fact that the USA, Japan, and Germany are facing nearly the same major demographic imbalances. In all three countries the baby boom after World War II carries a similar age structure for them. “The post-World War II baby boom and its echo (a subsequent baby boom after 25 years, as the boomers themselves had children) profoundly destabilized the age structure, for variable periods of time, in many developed countries”, so Bloom and Canning [6].

Focusing the USA we can state that the population has been relatively/high/low/balanced in the first half of 20th century. Since the 1950ies we can observe that the United States are in the middle of a dramatic demographic change which replaces the younger age structure with an older one. So a reduction of the 0-19 aged people from 33.9% in 1950 to 26.0% in 2050 accompanied with an increase of 65+ aged people from 8.1% in 1950 to 20.6% in 2050 can be expected [7]. The median age will change from 30.0 years in 1950 to 41.1 years in 2050 [8]. For Japan we can state an even more radical change in the share of elderly aged people growing. In regard to Kozu, Sato, and Inada the shift of the age-pyramid to an age-mushroom is even stronger than in the USA [9]. The data from the United Nations shows that the median age of 1950 of 22.3 years is getting up to 54.9 years in 2050 [10]. “Europe is frequently called the old continent and it truly deserves this name in a demographic sense” [11]. So the “UN World Population Prospects: The 2006 Revision” gives us a changing median age in Europe from 29.7 years in 1950 to 47.3 years in 2050. One of the strongest marked changing in the age structure of population in Europe has to be challenged by Germany. So we can state a shift of the median age of German population from 35.4 years in 1950 and over 39.9 years in 2000 up to 49.9 years in 2050 [12]. The following explanations, figures, tables and data are corresponding to the case of Germany. An adaption and transfer of theory and the analyzed data on the USA, Japan as image of Western industry nations will given in the ensuing section.

To reverse this demographic trend Höhn, Mai, and Michel state two demographic options, higher net immigration and the rising of fertility. Taking a look at the second named option the absence of potential mothers and fathers determines the shrinking German population of the next decades. In the long run a higher fertility seems to be more efficient than higher migration (Table 1 shows a much stronger impact on the age structure through fertility than through migration). In comparison within the alternative regarding higher immigration the dependency ratio increases to 85 up to 2050 rather than to 91 in the references scenario [13].
Of course this development has strong effects on firms and the economy as a whole. Taking the stated points in account two trends can be forecasted. Looking at the following table - trend 1 (Table 2) - and figure - trend 2 (Figure 1) - the two trends can be pointed out. Trend 1 is the changing population at working age, which will reduce their shares up to 2050 very intense [14]. Trend 2 of demographic change in German economy and firms intensifies the forecasted scenario. Not only that Germanys working population is shrinking but additionally that the resource workers are getting older and older. In this context the age related structure of human resources will be critically diversified towards an older population in general and so concerning the economic system to elderly employees in future [15].

Table 2: Demographic Projections for the Population at Working Age in Germany
“Perhaps the most imminent problems of aging will show up on the labor market” [16]. The cause of the fact that a deep decrease of working age people will face Germany from 2015 on - as the USA, Japan and in general Western industry nations - strong influences on the gross domestic product (GDP) can be expected. The decline of people at employable age, assuming a constant employment rate, labor participation rate, as well as the number of workers would shrink equal in future, the trend of labor productivity will continue and will bring a changing demographic structure along that limits the annual growth of gross domestic product (GDP) and growth domestic product (GDP) per capita by circa 1 % up to 2020 and by circa 0.5 % between 2020-2030. So there can be a rising of indirect costs through the demographic change through the negative influenced labor market as the differences of a possible but not realized future gross domestic product (GDP) [17].

Despite to the macro level effects on economic systems we can take a more detailed look at the micro level, the firm level through at the perspective of direct and indirect costs of work-related diseases. As figure 2 clarifies there are direct and indirect costs of work-related diseases on the left side concerning a physical workload and on the right side regarding a psychic one.
As workers' direct costs we state the therapy against diseases and indirect costs as productivity breakdowns due to work-related diseases through unemployables. Physical workloads we can describe as physical strains such as heavy liftings and as psychic workloads time pressure and stress. Statistical relevant for the current analysis is that the illustrated data must not be aggregated, because they are not independent from each other. We can suppose rising costs of work-related diseases through aging staff within Germany up to 2050, when we adopt the often proven hypothesis, that the older human resources grow the bigger the chances of getting limited by most of the relevant diseases, as the starting point of the underlying working context.

Taking a detailed look at the data, figure 3 shows that one third of all work related diseases emerge through ailments in the skeleton and muscular system. Furthermore looking closer at the data we can see a strong position of the back of the personnel. Beyond these respiratory organs and psychiatric diseases are shown to be relatively high in comparison to the rest of the analyzed data. For the reviewed diseases we monitor an increase accompanied by an older growing workforce for firms in Western industry nations. Especially in the direct areas of production an over proportional enlargement of diseases of skeleton and muscular systems as well as back disorders can be validated in regard to elderly workers compared to younger ones. For that reason of relative similar correspondence in age structure and the changing of the population we can project similar evolutions. Specially the mentioned cases above of the US, Japan and Germany are examples addressing other Western industry nations [18].

![Figure 3: Diagnosis Specific Direct and Idirect Costs of Work-Related Disease in Germany in 1998 (in Billion €)](image)

"Demographic change as it is nowadays observed in many developed countries is largely unprecedented. There are thus certain limitations to systematically analyzing its economic and fiscal consequences." Making the next step for the underlying research paper the analysis of macro and micro level costs of Western economy systems and its firms a second step in that direction will be made through some basic implications for managing the demographic change in organisation of Western industry nations. In the following section the critical points of designing working systems, health, education, and culture are the central challenging topics. Although the analyzed data mainly concerns the actual situation in Germany, some interesting implications for the USA, Japan and Western industry nations in general can be made.
3. BASIC IMPLICATIONS FOR THE MANAGEMENT OF DEMOGRAPHIC CHANGE

In regard to the discussion of the economic conditions of demographic changes in firms of Western industry nations there are two ways of how to continue. Either the addressed countries will follow the approached path of youth oriented personnel and corporate strategy or they challenge the systematically development of elderly but anyhow with competitive units. It seems to be obvious that the first way of going about it can be stated as deadlock. Following the first option, as shown within the analyzed data and cost analysis above, will bring next to the shortage of skilled workers a negative age-related impact on the productivity of firms and in all Western industry nations. So the only way out of this deadlock seems to be the second option. The critical question is how to develop systematically older growing but competitive firms further on [19]? 

The first two starting points can be directly answered through the analysis above. To the fact that the biggest amount of work related diseases can be detected in the fields of skeleton and muscular system as well as in the field of back disorders, the possible implications for management illuminates, 1) the ergonomic, age-oriented design of working systems, and 2) the active promotion of the staffs health.

1) In the ergonomic, age-oriented design of working systems we have to differ between the direct and indirect divisions of firms. The direct area refers to the more relevant and bound costs, the production area to firms. Possible objectives to design the working systems more age-oriented are to reduce critical sizes like heavy lifting, frequent bending and constant work footing as well as giving the relevant workers lifting pins. But also the situation in the indirect area, the administrative departments, can be improved through ergonomic changes. To first thing thinking of is to give the employees an adequate work place like appropriate office chairs, desktops and monitors. All in all the huge field of ergonomic designing of firms in the direct as well as the indirect divisions is essential. Everything considered as general objective is to reduce working places, which are posing a risk to the health of workers and employees for an older growing but competitive firm.

2) The second statement pointed out above is to generate a proactive health care in industrial firms. Therefore an effective health and safety protection at work seems to be crucial in this nexus. Regarding this the focus lays on the prevention of health management and disease. On the one hand we can state the valuation of working conditions here as a basis for a health-oriented and age-oriented design of working places / processes as relevant. On the other hand it is important to inform the staff about health risks. Add itional trainings for health-oriented behaviour is significant e.g. how to lift and to carry things. Constantly provided health checks for the staff, a regularly accomplished supervising through a company’s medical office and the active support of sport and wellness activities round of the possible options to the demographic change and health care. Managers should bear in mind that the importances of health care on work and in and with the ergonomic, age-oriented design of working systems.

Despite to the direct influences of managing the demographic change and reducing costs of older grown personnel, two more points lay open in literature to attack, 3) an age-related education in terms of long life learning, as well as 4) a corporate culture, which sees older employees as a benefit and not as a thread for staying competitive.

3) Next to the already stated points strong in vestments in the age-related education of firms’ employees is a profitable point. Tw o different but complementing ideas of e ducating concepts have to be discussed a s the long-life learning is not an empty phrase. Ad equate fo rms of f urther e ducation and training an d ex panding the current knowledge pool organized for older growing people help firms to stay competitive. In addition special forms of trainings, which support the work experience knowledge of older employees seems to be important. Here we suggest some intra-firm tools like “lessons learned”, “communities of practice (COP)”, an d knowledge-based exchange platforms as meaningful. To maintain the experience knowledge of older people is an important task for the firms s it i s extraordinary important that competitive success should be systematically managed for a sustainable future. The second complementing point is to adapt further education and training to the challenges and special conditions of older people. The rising complexity of the environment in combination with the constantly increasing information exchange has to be thematized in connectivity with age-oriented forms of learning.

4) According to our analyzes as well as to theoretical works we called the continuation of the approached path of youth oriented personnel and corporate strategy in the current situation of demographic changes as deadlock. Nevertheless most companies and industries do not act in this direction. But firms will be forced to rethink their behaviour in the next decades. To manage demographic change in total it i s absolutely necessary to generate a
pattern of basic assumptions [20], a mental programming of people [21] that sees elderly staff not as a threat but as a chance to stay competitive in future economic systems of Western industry nations. For cultural development in this direction socialization through company’s management, which would give an positive example, is the crucial starting point. To follow age-oriented personnel, corporate strategy and to communicate and live it in firms is the only way to start with this important point.

For the four called possible starting points the actual and future demographic situation, the above conducted analysis of data and costs, considerations in the scientific theory [22] as well as institutions as the “International Monetary Fund” (IMF) and the “Organisation for Economic Co-Operation and Development” (OECD) gives evidence, so that they can be seen as fruitful influencing variables to manage the demographic change in firms of Western industry nations.

4. SUMMARY

The main objective of the underlying paper was, based on the analyzes of the data regarding the demographic development and connected costs, to give firms possible starting points for managing the demographic change of Western industry organisations. Looking at data of the USA, Japan, and especially Germany the analyses gave us an idea how radical the demographic change and therefore common challenges for Western industry firms will be. Deducing costs out of this basis shows the importance for firms in Western industry nations to manage this evolution systematically for staying successful and competitive in future. Regarding these costs which mainly result out of work-related diseases e.g. of the skeleton, muscular system and back disorders some basic implications for firm’s management for demographic change can be given. 1) The ergonomic, age-oriented designing of working systems, 2) the active promotion of health, 3) age-related education and 4) a corporate culture, which sees older employees as chance and not as a threat were argued as possible answers to the question how to develop systematically older growing but competitive firms.

With this paper we made a critical step how to manage the actual and future noticed demographic change in Western industry firms, to get a human resource base which belongs to the different age structure to gain sustainable competitive advantage. Although the data of Germany is similar for the situations in the US and Japan, the results cannot be simply transferred in general, but needs to be strengthened in this context. Furthermore a more detailed look at the analyzed data can be seen as future research field to get new and more proven insights in general and especially in their connectivity to one of each other. Last but not least more detailed work for the four suggested determinants of managing the demographic change working systems - health care, education, and corporate culture - has to be done. On the one hand they have to be developed more sophisticated and on the other hand their reciprocal dependences must be analyzed with a more focused look.

Analysis of the Methods Time Measurement (MTM) Methodology through its Application in Manufacturing Companies

Denis L. M. de Almeida¹, João C. E. Ferreira¹

¹Departamento de Engenharia Mecânica
Universidade Federal de Santa Catarina, GRIMA/GRUCON, Caixa Postal 476
Florianópolis, SC, 88040-900, Brazil

ABSTRACT

With the continuous growth of competitiveness among companies, the increase in productivity has become an important requirement for many of those companies. However, it is important to think about alternatives that allow the increase in productivity without overloading the resources, avoiding equipment errors and health problems of the operators. In order to increase productivity, this work proposes the use of the Methods Time Measurement (MTM) methodology. This work analyzes the application of this methodology in manufacturing companies considering the current developments of time tables, which are not widespread in many companies. However, in this work the MTM methodology will not be applied in an isolated way, but in combination with other techniques. Details are given with regard to the methods and results obtained through the application of MTM in two companies of the automotive sector, and a company that manufactures household appliances. Finally, it is concluded that the MTM methodology is a useful tool for the planning and organization of operators’ working processes, and that combined with other applied methods it can generate a significant increase in productivity.

1. INTRODUCTION

We live in a world with scarce resources, and society is less and less accepting to pay the high price of waste. In order to be successful, companies need more and more to eliminate waste so that products with greater quality, lower costs, and shorter production times are provided to customers. Besides the high competitiveness among companies and the ever-increasing level of customers’ demand, the increase in the conscience of the workers about their contribution to the final product lead to a scenario where high productivity and responsiveness levels are mandatory. Thus, it is necessary the development and application of techniques that allow the best utilization of the available resources.

In order to increase productivity, this work proposes the use of the Methods Time Measurement (MTM) methodology in different companies.

MTM [1] defines the MTM methodology as an instrument to describe, structure, configure and plan work systems through defined process modules, seeking to be an efficient pattern of production systems. It can be used anywhere where it is necessary to plan, organize and accomplish a human task seeking its effective execution. Basically, "the method determines its time". When used for planning issues, the MTM methodology would justify the premise presented by MTM [1], which is to "avoid costs instead of reducing them", that is, a correctly planned process can be executed since the beginning without the extra costs associated with the inefficiencies of the process.

However, in spite of being a very useful tool, the MTM methodology, in its current stage of development, is still little known in countries like Brazil, which generates inadequate interpretations regarding its application. According to Priemer [2], manufacturing engineering and workers in Brazil, when they refer to the MTM methodology, make the following comments: "it is just a Taylorist method", "we don't know about it", "it is not applied in our production", "it is applied at the head office (abroad), but not here", "it is very detailed and it needs an excessive effort", "maybe it can bring us advantages."

2. METHODS TIME MEASUREMENT - MTM

The MTM methodology is a method to structure sequences of movements into basic movements [3]. The value of a standard time is assigned to each basic movement, which is (pre) determined as a function of the factors that influence its composition. The MTM methodology can be applied to: configuration of the work methods and products; determination of times; to describe the method as a form of documentation for training [3].

The MTM methodology is based on the following five basic movements: to reach, to grasp, to move, to position and to release (see figure 1) [3]. These movements compose 80% to 85% of the procedures wholly influenced by human beings. Besides these basic movements, the following actions are used to describe the movements: to apply pressure, to separate, to twist, body movements and visual functions. The body movements are divided into: foot movements, leg movements, lateral step, body spin, walk, bend, leave the bent position, lower, leave the lowered position, kneel on one knee, leave the kneeling position on one knee, kneel on two knees, leave the kneeling position on two knees, sit down, leave the seating position.

The MTM methodology is in continuous development. Some of the world developers of this methodology, always based on the basic method, are as follows:

• GPD (MTM-General Purpose Data - 1963) – American MTM Association;
• MTM-2 (1966) – Swedish MTM Association, being used in Scandinavia, England and France;
• MTM-SD (Standard-Daten-Basiswerte – Basic Values “Standard Data” MTM);
• MTM-UAS (Universelles Analysiersystem – Universal Analysis System);
• MEK (MTM für die Einzel- und Kleinserienfertigung – MTM for individual production and for small series).

3. METHODOLOGY

According to Sugai [4], the process of applying MTM should be considered as a process of continuous improvement, and it points out six stages for its application in a work station and four stages for its application in a company as a whole, which can be summarized in figures 2 and 3, respectively.
In this work case studies of the application of MTM in three companies were analyzed, being two car companies and a company that manufactures home appliances. A German plant that manufactures cars was evaluated, whereas the other two companies were evaluated in Brazil.

For the accomplishment of the MTM analyses, the following data sources were used: (1) direct observation of the work station by MTM analyst; (2) analysis through films; (3) documents (such as process plans and technical data about the products); (4) simulation of the movements by the MTM analyst; (5) experience of the operators and process planners. The choice of which sources would be used depends on the availability of these data and time to accomplish the analyses.

Once the data is collected, they were evaluated through the TiCon software [5], which was also used to balance the activities. However, this work was not limited to accomplish time analyses, but it sought to combine the MTM methodology with other methods to allow the productivity increase in the evaluated areas.

The work to increase productivity consisted in: (a) to determine the correct times for each activity; (b) to study the work stations seeking for better solutions and methods; (c) to redistribute the activities in order to level the line; (d) to propose improvements; (e) to priorize and implement improvements; (f) to train operators; (g) to validate the proposals. Besides the stages above, audits correspond to an additional stage that can be applied in any of these stages to guarantee the application of the proposed methods.

It was verified that the greatest potential of the MTM methodology is in the possibility of combination with other methods, since through the detailing of the activities failures and waste that would pass unnoticed by other techniques would be identified by MTM. In this study, some techniques were verified in practice that could be combined with the MTM methodology, which helped in the search for better methods and improvement proposals, and these techniques were:

1. **To standardize:** Some of the main patterns verified in the evaluated car companies are: work in one takt; fixed cycle times; reference point in the products; movement in triangle; materials made available in the station area; avoid blocking the movement; alarms of quality problems and alarms of line stoppage; use of limited equipment
within the station; target of percentage of added-value activities; avoid processes that require more than one operator; transportation devices to guarantee ergonomic stations; use of "andons."

2. **Layout:** Besides allowing the improvement of the transport, the improvement of the layout is directly linked to the ergonomic improvement of the work stations.

3. **Use the data supplied by the MTM methodology:** from the analysis of the information supplied by the MTM methodology, questions can be made in order to verify and implement improvements.

4. **Study the processing/waiting times:** the time that an operator waits for a machine to accomplish its process is waste, and as such it should be eliminated.

5. **Prevent a local improvement from worsening the global situation:** because the MTM method focuses on the local activities.

6. **Use the experience of the operators:** the fact that the operators work directly at the place to be analyzed and they experience the problems daily makes them a source of valuable knowledge for the company.

7. **To outline the process:** an outline of the process can be used as a summary of the relevant information to allow a fast and simple visualization.

8. **To motivate the search for group solutions:** The work in groups is extremely useful to find solutions for improving the process.

9. **Support employees:** the multifunctional operators are very important for the production lines, since they significantly help to level the production lines by the elimination of disturbances.

10. **Another means to optimize a process:** The proposals listed above correspond to only some of the possibilities of improving a process, but to limit these techniques into a list, no matter how complete it is, it can be considered inadequate, since the human creativity is limitless, as well as the possibilities to improve a process. Therefore, the techniques pointed out here should be used as a guide and not as a general rule to improve the process, since many other possibilities may be implemented successfully.

In the three analyzed companies, several situations could be evaluated through MTM, such as: alterations in the production volumes; activities that combined line-based and cell-based work stations; quality control, finishing, and rework activities; activities with multiple combinations of variants, logistics, etc. The MTM methodology led to good results in the evaluation of all these cases, but two cases that recurred in all the companies considered, which will be highlighted here, were the following: the comparison between MTM and times obtained though chronometer measurement analysis, and the analysis of simple/repetitive activities.

4. **CASE 1: COMPARISON OF MTM WITH CHRONOMETER MEASUREMENT ANALYSIS**

The comparison between the times obtained by the MTM method and those obtained with the chronometer measurement analysis took place several times during the MTM applications considered in this work. The following example presents the result of a comparison between a MTM analysis and the result of a simple chronometer measurement.

A versatile operator acts at three work stations "A", "B", and "C", each one with cycle times equal to 90 seconds, calculated based on the production demand. The supervisor responsible for the area, not satisfied with the results of the MTM analyses, decided to time the operator to verify the times. By simply timing the operations, but not performing a complete chronometer measurement analysis, the supervisor declares that the MTM times were not in agreement with the real situation, and he mainly criticizes station C, where the time of MTM analysis was almost 10 seconds lower than the timed one. Table 1 shows the results described above.

<table>
<thead>
<tr>
<th>Work station</th>
<th>MTM Analysis</th>
<th>Chronometer Measurement Analysis</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>95.3 s</td>
<td>90.5 s</td>
</tr>
<tr>
<td>B</td>
<td>89.4 s</td>
<td>91.0 s</td>
</tr>
<tr>
<td>C</td>
<td>71.8 s</td>
<td>81.5 s</td>
</tr>
<tr>
<td><strong>Total Time</strong></td>
<td><strong>256.5</strong></td>
<td><strong>263</strong></td>
</tr>
</tbody>
</table>
When analyzing the data, the supervisor also questioned the fact that the MTM time for station A was longer than the MTM time for station B, while the result for the chronometer analysis was the opposite.

The MTM analyst then asks the supervisor regarding his/her opinion about the rhythm of work of the operator in the work stations. The supervisor replies: “In station C, the operator worked calmly, in station B in a good rhythm, but he was accelerated in station A”. The analyst then suggested the analysis of the data through the Operator Balance Chart of the work stations.

By observing table 1, it can be noticed that in the chronometer analysis measurements the times tend to the of 90 seconds line that refers to the cycle time. The reason of this phenomenon is related to the available time for the operator to accomplish the task. The operator has 90 seconds on average to perform the activities in each station, i.e. he/she will have to make a greater effort and to accelerate the rhythm to meet the required production in station A, but he/she reduces the speed and works in a more relaxed manner, in order to take advantage of the time in work station C. In station B, the measurements with chronometer and the MTM analyses reached similar values, and the main reason is the fact that the cycle time is approximately equal to the time of the activities, i.e. a correct MTM analysis will result in values very close to 90 seconds, and the operator will have to maintain a good rhythm to meet the needs of this work station. It can be inferred that the MTM analyses emphasize the different workloads at the station, since they do not suffer influence, for instance, of the pressure on the operator to accomplish his/her task in the correct time.

It should be emphasized that, if the chronometer analysis were performed adequately, repeating the measurements in the appropriate amount and applying the rhythm evaluation, the times would approach the times obtained by the MTM method, which can be verified in cases where the chronometer analysis was applied correctly.

5. CASE 2: ANALYSIS OF THE SIMPLE/REPETITIVE ACTIVITIES

This topic is based on the need to accomplish correct analyses in the shortest possible time. Britzke et al. [6] perform a comparison between the analyses accomplished with the GMA, GMA 2 and GMA 3 methodologies, which are appropriate modules for mass production, series production, and small series production respectively. This comparison can be extrapolated as reference for the modules MTM-1, SD, UAS, and MEK (pointed out in section 2), considering the following combinations: (a) GMA and MTM-1 for mass production; (b) GMA 2 and SD/UAS for series production; (c) GMA 3 and UAS/MEK for producing in small series.

Britzke et al. [6] point out that, for the GMA, GMA 2 and GMA 3 modules, it takes from 200 to 300 minutes to analyze 1 minute in the case of mass production, from 100 to 150 minutes for series production, and from 20 to 30 minutes for the producing in small series. In other words, the time necessary to perform an analysis for production in series should be approximately 50% of the time required for the analyses of mass production, and the time for small series should be equal to 10% of the time for mass production.

Those values should be considered only as reference, because it can be verified, when accomplishing the analyses, that there are several factors that contribute to reducing (or to prolonging) the analysis time, such as the following: (a) experience of the analyst with the methodology; (b) the knowledge of the analyst about the time tables to be used, as well as the time tables that served as reference; (c) the knowledge of the analyst about the stations to be analyzed; (d) the knowledge/experience of the analyst about similar work stations; (e) access to information (p.ex., film, direct observation, access to the operators, historical data, documentation, procedures with descriptions of the station’s activities); (f) level of the used method; (g) support from the people involved, and (h) the analyst’s personal factors (motivation, diligence, etc.).

Besides these factors, an aspect that influences significantly the speed of the analyses is the degree of complexity of the work station. For instance, an inexperienced analyst would probably have great difficulty in analyzing activities of finishing or those having multiple variants.

On the other hand, there are analyses that become simple due to the repetition of movements, which speeds up the execution of the analysis. A typical example of this type of analysis is the analyses of the work on press machines. Despite this type of work occurs in several different applications, it can be affirmed that in many companies such movements can correspond to 80% of the production movements (disregarding the maintenance activities, setup, etc.) when considering production sectors/teams dedicated to these activities.

The typical movements in this process are: (a) to grasp parts; (b) return movement from grasping parts; (c) to position the parts in the press; (d) to depress the bi-manual command (due to the existing risks and demands of the standards, the bi-manual command ends up being one of the most common cases of actuation); (e) process execution; (f) to grasp parts; (g) to deposit parts, and (h) return movement from depositing parts.

Table 2 presents an analysis of activities of the work in presses, based on the cases verified in practice.

6. MTM COMBINED WITH OTHER METHODOLOGIES

There are many methodologies that can be applied in parallel with the MTM methodology, and some of them were applied during the studies of this work, such as the kaizen workshops and the 5S philosophy. The main conclusion regarding this topic is that the MTM methodology is not competitive with other managerial tools, but complementary. The chronometer analysis, which many people consider as being competitive with the MTM methodology, is actually a good example of method that can be applied together with MTM.

In these cases, the chronometer analysis can be used as a counterevidence of the times evaluated with MTM and vice-versa. Another great possibility of combining these methodologies is the application of MTM to activities influenced by man, and the chronometer analysis for processes that depend on machine times. This logic can also be extended to other time measurement methods, such as the sampling and/or estimates of times that can be used, for instance, to evaluate the times that the operator needs to go to the bathroom, to drink water, etc.

Regarding the planning situations, the MTM methodology was very advantageous, and its use is strongly recommended as main method, but for series activities it is recommended the combination of MTM with other methods for time evaluation.

A frequent criticism to the MTM methodology by the people involved with analysis of times in companies is the time necessary to accomplish the analyses, but this point was proved wrong during the execution of this work. To avoid the long execution times, it is important to structure the analyses and the database of the production times of the company, which is usually accomplished in the chronometer analysis. This procedure enables the reuse of the data in future situations. With that structuring, it was verified that the MTM analysis can, depending on the situation, be faster than the chronometer analysis.

Considering only the MTM analyses in each day worked, the following was analyzed:

- Little more than 30 seconds of activities of the operators a day in the first weeks of performance, which is considered a low analysis speed, mainly due to the unawareness of the tables used in the considered company;
- Approximately 1 minute of activities of the operators a day, including the practical leveling (practical application of the results in the production line) in the following weeks;
- 6 minutes of activities of the operators a day after some months of applying the MTM methodology. This duration can be considered appropriate for analyses by trained MTM analysts, for the cases in which the company’s structure of times is ready.
• 12 minutes of activities of the operators per day in favorable cases after some months of applying the methodology.

For instance, comparing MTM with the chronometer analysis, which needs to measure 30 repetitions of the activities, in order to evaluate 12 minutes it would be necessary 360 minutes of direct measurement, i.e. 6 working hours, which implies that analyses such as rhythm evaluation and dismissal of measurements with errors, would need to be accomplished in little more than 2 hours to have a rhythm equivalent to the MTM methodology, not considering the data structuring for a subsequent reuse.

An important observation to be made is that these times were analyzed for serial activities, whose cycle time was equal to approximately 1 minute, and the time of method was equivalent to the SD / UAS tables. Different applications require different times for analysis.

Another observation is that the times presented here do not consider the bureaucratic processes of the companies, such as the need to report the analyses to the high management or collecting several signatures of specialists. These times were frequently superior to the times of analysis, and they should be taken into account when planning the application of MTM.

Similarly to the chronometer analysis, Lean Manufacturing can also be combined with the MTM methodology, because both have as objective the reduction of costs through the elimination of waste, but while the Lean Manufacturing focus the processes of the companies as a whole, the MTM methodology focuses on the manufacturing processes, with emphasis in the human activities.

An important issue considered by Lean Manufacturing that was applied in practice through the MTM methodology is the classification of the activities into value-added activities, non-value added activities (but are necessary), and waste. Another methodology whose combination with MTM can lead to significant gains in productivity is the rapid exchange of tools, as pointed out by Cakmakci and Karasu [7].

Besides the methods pointed out above, the MTM methodology was combined with other methodologies during the execution of this work, all with good results. Some of these methodologies were: 5S, Ergonomics, Continuous Improvement, PDCA Cycle, Kaizen Workshops, Benchmarking, SPC – Statistical Process Control, etc.

7. CONCLUSIONS

Regarding the developed work, the first observation is that the MTM codes and times are universal and guaranteed by IMD (MTM International Directorate). The practical observation proved that the times that are valid in Brazil are also valid in Germany, and this can be extrapolated to any part of the world, which can be proven through international contacts.

The MTM code helps significantly the understanding of the processes by somebody who does not dominate the language in which the descriptions are made. Somebody who knows the used code and can visualize the described process is capable of understanding the analyses even without understanding a word of the descriptions of the activities.

It could be verified that in a general there is a greater acceptance of the MTM methodology in Germany compared to Brazil. In Brazil, the MTM methodology is ignored in general by great part of the companies. One of the facts that can be used as proof of the greater acceptance of the MTM methodology is the fact that even in the companies that use MTM in Brazil, few people know the methodology, while in Germany this methodology is in general more widely known and applied.

When the MTM methodology is analyzed in an isolated way, it can be considered as a table of times, and as such it does not increase productivity. However, the need for detailing the tasks for its analysis process enables the identification of small wastes, which pass unnoticed through other improvement processes, and consequently MTM provides an appropriate base so that improvements may be implemented. The need for detailing the tasks contributes to reduce the effort required to accomplish the analyses, which was minimized with the most recent developments of the MTM methodology, where time tables were developed for different levels of methods.

After accomplishing this work, we conclude that the MTM methodology is a useful tool for planning and organizing work methods of the operators, and when it is combined with other methods applied by the companies it can lead to a significant productivity increase.

Also, the following additional conclusions can be pointed out:
• The operators should not work during more hours, but in an efficient way, in other words, the MTM methodology does not intend to reduce the time that the operator has for accomplishing a certain activity, but to eliminate the unnecessary movements that waste time;

• The main factors associated with the success of the implementation of the MTM methodology verified in this work were: company policy, support from company management, structuring of the data, and training of the operators;

\textbf{ABSTRACT}

Knowledge management (KM) has recently emerged as a discrete area in the study of organizations and frequently cited as an antecedent of firm performance. Managing the knowledge resources effectively and efficiently seems to be the only way to gain continuous and sustainable competitive advantage for organizations in the long-run. However, the concept of KM is still evolving and therefore, it is not easy to develop a theoretical framework that has been widely accepted. This paper analyzes KM practices based on eight dimensions including organization structure, technological infrastructure, organizational culture, intellectual property, knowledge generation, knowledge codification and storage, knowledge transfer and sharing, and knowledge utilization. A customized neural network model was developed to test the theoretical model based on a sample of 277 small and medium sized enterprises (SMEs) operating in textile industry of Turkey. Empirical analysis of the model showed that there was a strong and positive relationship between the level of KM practices and organizational performance. Further, managerial implications to improve the performance of SMEs were proposed in terms of KM practices.

1. INTRODUCTION

As one of the contemporary management tools, knowledge management (KM) has been increasingly used by most of the large-sized organizations and multinational companies to gain sustainable competitive advantage in the long run. Despite its growing implementation, the concept of KM is still evolving and, yet there is no unifying or overarching theoretical framework that has been widely accepted.

While KM has been frequently cited as an antecedent of organizational performance, there is a paucity of empirical research regarding the impact of KM practices on organizational performance. This lack of interest is even more pronounced in the context of small and medium-sized enterprises (SMEs). While implementation of KM practices in large size firms provides immense business opportunities in terms of achieving cost efficiency and gaining competitive advantage, there is less evidence of small- and medium-sized enterprises (SMEs) implementing KM practices to capture similar benefits. The question then remains open how well KM practices fit with the SMEs, which form the largest group of manufacturing firms in both developed and emerging market economies from the viewpoint of generating employment and economic growth (Demirbag et al., 2006). They account for more than half of the employment and value added in most countries (UNCTAD, 1993). Similar trend is also observed in Turkey where SMEs constitute 99.5 per cent of all business establishments and employ 61.1 per cent of the workforce (Yilmaz, 2004).

In view of the fact that the success of SMEs has a direct impact on the national economy, this study provides essentially two main contributions to SME research. First, based on a sample of SMEs operating in two sub-sectors of textile industry within the greater metropolitan area of Istanbul in Turkey, this study aims to examine the impact of KM practices on the organizational performance of SMEs. Second, the neural networks approach which has been gaining recently a growing interest in business research is also employed to identify the most important KM practices on organizational performance of SMEs.

The remainder of the paper is organized as follows. The next section briefly reviews the relevant literature on KM practices. Research methodology is presented in Section 3. Data analysis and results are provided in Section 4. Conclusions are in the final section.

2. LITERATURE REVIEW

The field of KM has recently emerged as a new area of interest for both academic and business circles. The literature reveals an increasing number of studies covering many different fields of KM (McAdam and Mcreedy, 1999). Along with this growing interest, there is a vast number of definitions with more or less common in characteristics (Lytras et al., 2002) emphasizing several different aspects of KM. The existing studies in the field of KM have largely focused on three major streams (Geisler, 2007): the nature; the processes of knowledge generation, sharing and distribution; and infrastructure for technology and effective management of knowledge. Zaim et al. (2007) classify the infrastructure further into four areas: technology, organizational culture, organizational structure and intellectual capital. Similarly they also identify four areas of processes for KM: knowledge generation and development; knowledge codification and storage; knowledge transfer and sharing; and knowledge utilization. In the forthcoming section, we will develop the concept of KM in line with the categorization purported by Zaim et al. (2007) and will subsume both KM processes and related infrastructure under the general heading of KM practices.

2.1. KM PRACTICES

It has been argued that the effectiveness of KM depends on how the generation of new knowledge is organized and how existing knowledge is transferred throughout the organization. Recent studies have expressed considerable interest in knowledge sharing practices (Hicks et al., 2007). The benefits of knowledge transfer and sharing have also been discussed widely among the scholars and practitioners (Sveiby and Simons, 2002). Therefore, one of the most important objectives of KM is to bring together intellectual resources and make them available across organizational boundaries. It has been suggested that organizations often waste their resources and lose a significant amount of money for repeating the same mistakes, duplicating projects and being unaware of each others’ knowledge due to the lack of knowledge transfer and sharing throughout the organization (Robertson, 2002).

Knowledge transfer is not a unidirectional movement. Effective knowledge transfer is more than the movement of knowledge from one location to another. Organizations can get significant learning experience through knowledge transfer between units and people. It tends to improve competency of both sides that transfer and share knowledge. It is because knowledge does not leave the owner when it has been transferred. As a result, the value of knowledge grows each time a transfer takes place and the key to value creation lies in how effective knowledge has been transferred throughout the organization.

The role and importance of information and communication technologies in knowledge transfer have been emphasized by many scholars. Clearly, technological advances bring a vast number of new opportunities to transfer and share knowledge and expertise throughout the organization within departments, plants, countries and across national borders. These technologies have a strategic role in knowledge sharing specifically for the geographically dispersed global organizations (Bender and Fish, 2000). The effective use of technologies creates new ways of knowledge transfer and hold promising solutions both in transfer of explicit knowledge and tacit knowledge – in terms of experience and expertise- (Jacop and Abrahampur, 2001). In this respect, it is often mentioned that technological infrastructure has a strategic importance in knowledge transfer not only within the organization but also among different organizations (Zhao and Xie, 2002).

As a matter of fact, all healthy organizations generate knowledge. While they are interacting with their environment, they absorb information, combine it with their experiences, values and internal rules, turn it into knowledge, and take action based on it. Knowledge generation can be performed in many ways. The three of the main modes amongst others are knowledge acquisition, knowledge generation within the firm and collaborative knowledge generation. However, knowledge generation process is a set of activities for the conscious and intentional generation of knowledge under specific actions and initiatives firms undertakes to increase their stock of corporate knowledge (Davenport and Prusak, 1998).

Knowledge generation process does not necessitate new knowledge generation. In many circumstances, organizations may prefer to acquire knowledge from other sources and adopt it for their own use (Bhatt, 2000). Knowledge acquisition can be used for knowledge creation, and if it is novel and useful for the organization, also be considered as a part of knowledge generation. Organizations convert information they collect from internal and external sources into knowledge through their organizational learning process by combining it with their prior
knowledge, experiences, values and organizational procedures (Hong, 1999). Then, the knowledge becomes a part of their organizational knowledge base. This obviously explains why the knowledge acquired through these organizational processes is new and unique for that organization (Krogh and Roos, 1996).

Knowledge is meaningful when it is codified, classified, put in a useful format and stored. Only then, it can be used by the right person, at the right time and in the right way. Knowledge codification and storage is important not only for an effective use of knowledge but also for reusability of knowledge in case it is needed so that the knowledge in question can be internalized to the organization rather than the knower (Nemati, 2002). Therefore, considering the organization’s overall objectives and priorities, many studies have been concentrating on the classification and the codification of knowledge based on its types and purposes (Lueg, 2001), and on the storage of knowledge to let the employees be able to access knowledge any time both at present and in the future. The codification of knowledge also enables to stock the knowledge resources and to assess the potential of the organization. The most challenging feature of knowledge codification is to gather it without losing distinctive properties which makes it valuable (Davenport and Prusak, 1998).

Despite its importance, codifying and classifying knowledge is not that simple since it relies heavily on what people know. Thus, organizational knowledge is hard to capture, clarify and express perfectly fine considering the fact that it is dispersed and scattered throughout the organization. It is found in different locations, in peoples’ minds, in various organizational processes, in corporate culture embedded into different artifacts and procedures and stored into different mediums such as print, disks and optical media (Bhatt, 2001).

There is a distinction between tacit and explicit knowledge in the storage of knowledge. Explicit knowledge can be easily collected, documented, stored and retrieved quite independently of any single individual through technological means and systems. On the other hand, tacit knowledge resides in the minds of the employees and seizes a great deal of an organization’s knowledge resources (Drott, 2001). If the organization’s knowledge resources have been described as an iceberg, the explicit knowledge is the visible part of the iceberg above the surface, whereas the tacit knowledge includes the invisible part of the iceberg beneath the surface (Herrgard, 2000). The codification of tacit knowledge unlike explicit one is the most cumbersome activity in the overall process because of its subjective and situational nature, and it is intimately tied to the knower’s experience.

One of the most important and challenging aspects of KM is to enhance the development of a collaborative, trustworthy, emphatic and helpful organizational culture. The executives and scholars agree on the importance of a knowledge-friendly culture for the success of KM (Hauschild et al., 2002; Skyrme, 1999). It is because knowledge is a context-dependent social concept (Lang, 2001) and a large part of organizational knowledge is embodied in social processes, institutional practices, traditions and values (Fayard, 2003; Boisot, 1998). Therefore, no matter how powerful the tools and functions of KM are, it is of no use without willing participants and a supportive social and cultural environment (Koulopoulos and Frappaolo, 1999). While the cultural resistance is generally cited as one of the most important barriers to an effective implementation of KM (Sveiby and Simons, 2002), it is still contemplated as the neglected or underestimated side of KM practices. Therefore, it is strictly recommended for organizations to place a special emphasis on the social and cultural issues for the successful implementation of KM practices (Bhatt, 2001).

The appropriate organizational structure and guidelines as well as technical and non-technical expedients of which the organization has disposal constitute another building blocks of KM infrastructure (Beijerse, 1999). Nonetheless, there is no single appropriate organizational structure for KM. Some scholars suggest a radical re-design for KM (Malhotra, 2000), while others think that it is not necessary. However, instead of highly centralized, control-based and rigid hierarchies, more flexible, decentralized and trust-based organizational structures with empowered workers are highly recommended in the KM literature (Maier and Hadrich, 2006; Malhotra, 2005).

One of the most important objectives of KM is to create value from organization’s knowledge resources so that the knowledge held by the company can be transformed to fields of application and action (Ordaz et al., 2004). This implies the effective and efficient knowledge utilization for the organization’s competitive edge. For that reason, it has been argued that the success of KM practices mostly depends on how efficient and effective the knowledge has been used and the level of action based on it (Wilhelmij and Schmidt, 2000).

The KM literature clearly exposes that knowledge resources have been increasingly seen as an integral part of organizations’ value creating processes. In a similar vein, companies have become aware of the importance of intellectual capital of their own (Guthrie et al., 2003). Intellectual capital can be defined as ‘the sum of all the intellectual materials of a company’ – knowledge, information, intellectual property including trademarks, patents and licenses, experience and integrity, personnel competencies, collective brainpower, etc. – that is captured and leveraged to create value and that can be converted to wealth and profit (Stewart, 2001; Harrison and Sullivan, 2000; Bontis et al., 2000). Though there are a variety of different components that constitute intellectual capital, an
increasingly popular classification divides intellectual assets into three categories: human capital, structural capital and customer capital (Skyrme, 2002).

2.2. PERFORMANCE

The main objective of KM performance evaluation is to increase the effectiveness, efficiency and adaptability of KM efforts so as to add more value to the overall performance of the organization (Toften and Olsen, 2003).

Given the general rule about performance evaluation that performance improves through evaluation, it is reasonable to argue that measuring the outcomes and evaluating the contribution of KM practices are important to ensure the sustainability and success of KM efforts over time. Without assembling the link between desired outcomes and KM practices continuously and demonstrating tangible or quantifiable intangible results, it is not possible for the top management to keep on investing and for the workers to preserve their concentration and motivation (O’Dell and Grayson, 1998). Apparently, evaluation of KM-related organizational performance also shows to what extent the intellectual resources of a firm have been utilized (Firer and Williams, 2003; Marr et al., 2003) as well as the degree of the conversion of the organizational knowledge into improved performance (Kalling, 2003).

3. RESEARCH METHODOLOGY

3.1. SURVEY INSTRUMENT

Data were gathered via cross-sectional mail survey using a self-administered questionnaire that was essentially composed of questions related to KM practices and organizational performance. Respondents were asked to indicate the level of agreement based on five-point Likert scales ranging from 1 “strongly disagree” to 5 “strongly agree” on each of the items measuring eight aspects of KM practices, which include organizational structure (OS), technological infrastructure (TI), organizational culture (OC), intellectual capital (IC), knowledge generation (KG), knowledge codification and storage (KCS), knowledge transfer and sharing (KTS), and knowledge utilization (KU). All eight KM practices are essentially multi-item scales derived from a total of 28 items. While KTS and OS are measured by 7 and 5 items respectively, the following four KM practices including KCS, KU, KG and TI are all measured by 3 items. Both OC and IC are, however, measured through two items. Inter-item reliability measures of all 8 KM practices are well above the threshold value of 0.50 for surveys of exploratory nature as suggested by Nunnally (1978). Regarding the organizational performance related to KM, respondents were asked to rate to what extent KM practices have led to improvement on each of the following four organizational performance criteria over the last three years: overall organizational performance, usability of KM applications, overall employee performance and having a common sense of corporate mission. These organizational performance criteria related to KM practices were measured using five-point scales ranging from “definitely better” through “about the same” to “definitely worse” or “don’t know”. An index measure (PERF) composed of these four items captures the SME’s organizational performance in terms of KM practices ($\alpha = 0.87$).

The questions with regard to the study’s variables were derived from the extant literature and discussions based on semi-structured interviews with a number of senior managers from three SMEs. The questionnaire was pre-tested several times to ensure that the wording, format and sequencing of questions were appropriate. Occasional missing data on variables was handled by replacing them with the mean value. The percentage of missing data across all data was calculated to be relatively small.

3.2. THE SAMPLE

In line with small business research, this study adopted the number of employees as the base for the definition of SME. An SME is identified as one that employs fewer than 250 employees. The minimum of at least 10 employees was also chosen in order to exclude micro firms that would not be suitable for the purposes of this study. A self-administered questionnaire was distributed to 500 SMEs operating in textile industry within the greater metropolitan area of Istanbul in Turkey. For centuries being the largest city of Turkey, Istanbul has been undisputedly the main industrial and trade centre which accounts for nearly 75 per cent of total capital investment generating nearly 23 per cent of Turkish GDP (Berkoz and Eyuboglu, 2005). This sample was selected randomly from the database of Turkish Small Business Administration (KOSGEB). As of 2005, the KOSGEB database includes a total of 12,270 SMEs in the greater metropolitan area of Istanbul, which accounts for nearly 28% of all SMEs registered throughout Turkey. The sampling frame consists of 2,482 SMEs operating in the textile industry including textile mill products
and apparel (SIC codes 22 and 23), since it has been a leader in implementing progressive quality management practices in Turkey. The textile industry has also been the engine of economic growth and generates the largest volume of export revenues. Although one could argue that a focus on a single industry may make the results less generalizable, we ensured a high level of internal validity. Furthermore, within the textile industry there exist several different manufacturing environments and product types making the sample much more diverse than what could be expected for a homogenous sample.

It was requested that the questionnaire be completed by a senior officer/executive in charge of HRM and KM practices. The responses indicated that a majority of the respondents completing the questionnaire were in fact members of the top management. Of the 500 questionnaires posted, a total of 293 questionnaires were returned after one follow-up. Sixteen questionnaires were eliminated due to largely missing values. The overall response rate was thus 55% (277/500), which was considered satisfactory for subsequent analysis.

4. DATA ANALYSIS

The data analysis was conducted in two steps: First, we conducted a reliability analysis to check unidimensionality of each of the KM practices. Second, we measured the impact of each KM practice on the overall organizational performance using neural networks (NN) model.

4.1. UNIDIMENSIONALITY TESTS OF KM PRACTICES

The reliability of eight dimensions of knowledge management application was assessed by checking unidimensionality of each construct using two tools: Cronbach’s alpha and Dillon-Goldstein’s ρ (Chin, 1998). All of the Cronbach alpha values met the minimum threshold value of 0.70. Similarly, Dillon-Goldstein’s ρ analysis provides ρ values that are well above 0.70 for each construct supporting unidimensionality.

4.2. NEURAL NETWORK ANALYSIS

Recently, there has been a growing research attention in the development of artificial neural networks for solving a wide range of problems from different fields. Neural networks are distributed information processing systems composed of many simple computational elements interacting across weighted connections. Inspired by the architecture of the human brain, neural networks exhibit certain features such as the ability to learn complex patterns of information and generalize the learned information. Neural networks are simply parameterized non-linear functions that can be fitted to data for prediction purposes (Haykin, 1994).

The main appeal of neural networks is their flexibility in approximating a wide range of functional relationships between inputs and output. Indeed, sufficiently complex neural networks are able to approximate arbitrary functions arbitrarily well. One of the most interesting properties of neural networks is their ability to work and forecast even on the basis of incomplete, noisy and fuzzy data. In addition, they do not require a priori hypothesis and do not impose any functional form between inputs and output. For this reason, neural networks are quite practical to use in the cases where knowledge of the functional form relating inputs and output is lacking, or when a prior assumption about such a relationship should be avoided.

A neural network (NN) model used in this study has been developed in MATLAB to identify the most critical dimension of knowledge management for organizational performance of Turkish SMEs. To train and test the model, the data set was divided into two classes namely training and testing data sets. As a result, from the whole sample of 277 SMEs, 209 (75%) were selected randomly as training data, while 69 (25%) were selected as testing data.

The success of the NN models depends on properly selected parameters such as number of hidden nodes or neurons (HN) and layers, the nonlinear function used in the nodes, learning algorithm, initial weights of the inputs and layers, and the number of epoch the backpropagation model is iterated. The structure of the proposed NN model is shown in Figure 1, which consists of one input layer, one hidden layer and one output layer. Since there are 8 input variables denoting the KM practices, 8 nodes are placed at the input layer.
By changing the number of nodes (1 through 5) during the testing of the model, it is decided to use three nodes at the hidden layer, where the minimum mean square error (MSE) value occurs at this point for the training data set. As shown in Figure 2, the MSE values decrease for both the training and testing data sets when three nodes are used in the hidden layer. If there are more than three nodes at the hidden layer, it is possible to talk about the overtraining of the model. Thus, the network and its associated connection weights are set at this point and organizational performance according to NN model is estimated using these weights.

A hyperbolic tangent sigmoid and a linear transfer functions are used in the hidden and output layers, respectively. Levenberg-Marquardt backpropagation algorithm is applied to train the NN model since it trains faster, requires less memory and is not sensitive to learning and momentum rates. Also, the weights are initialized using the Nguyen-Widrow layer initialization method.

The performance of the NN Model is evaluated using MSE and R-square values. The best performance scores are estimated for the NN model with three nodes at the hidden layer. The MSE values for this model are calculated as 0.306 and 0.737 for training and testing data, respectively. The R-square value is found as 0.56, which could be
accepted as highly satisfactory due to imprecise nature of the data. Figure 3 shows the comparison between the NN estimations and exact values of the test data.

Figure 3: Comparison of NN model estimates with target values.

Assuming that NN model has an acceptable capability of predicting the organizational performance, the impact of KM dimension on firm performance may be evaluated and ranked based on the same model. This also provides managers with invaluable information in identifying which KM practices they should concentrate in order to have a better organizational performance. Table 1 shows the contribution of KM practices to the organizational performance in terms of the degree of their importance levels and their respective rankings. From the full set of 8 KM practices, knowledge transfer and sharing (0.147) appears as a leading factor, which is also in line with the existing KM literature. Technological infrastructure is the second most important criterion with the importance level of 0.140, while knowledge codification and storage is found to be the third important KM practice with the importance level of 0.139. In contrast, intellectual capital and knowledge generation are the least important KM practices in terms of their effects on organizational performance. This finding is not particularly surprising that KM practices have been primarily focused on knowledge transfer and sharing and technological infrastructure in SMEs.

5. CONCLUSION

This study has investigated the relationship between the implementation of KM practices and organizational performance. While it has been generally accepted that KM practices tend to enhance organizational performance, there is a paucity of empirical evidence to verify this link especially for SMEs. Our analysis provides a significant support to the contention that implementation of KM practices have a positive impact on the KM-related organizational performance of SMEs operating in Turkish textile industry.
Our findings indicate that the most important KM practices which influence organizational performance are namely knowledge transfer and sharing and technological infrastructure. KM practices and efforts for SMEs operating in textile industry have been primarily focused on sharing existing knowledge rather than knowledge generation. However, it should be recognized that the factors involving the KM processes are interrelated. That is, in order to improve knowledge sharing, the other factors should also be considered as a whole.

Nevertheless, the outcomes of this study are only valid for SMEs operating in textile industry of Turkey. As a further research area, a similar study can be conducted in different industries, and an industry wide comparison based on KM practices would enable to construct a KM map of the country. There is also a need to undertake comparative surveys examining the differences in KM implementation and their effect on organizational performance in SMEs and large-sized enterprises along with considering the other contextual and moderating factors affecting KM-performance link.

A Metric for Rating the Effectiveness of Installed Industrial Automation Systems using an Adjusted Function Point Analysis

David W. Russell

Division of Engineering and Information Science
Penn State Great Valley
Malvern, PA 19355, USA

ABSTRACT

This paper describes the design of a factory automation performance and satisfaction metric that is based on variations to the function point analysis algorithm used in software engineering and the analytical hierarchy process methodology common to systems engineering. The paper asserts that a satisfaction rating can be obtained for completed automation projects based on this tautology. The metric uses five high-level functional ratings which are subdivided according to complexity criteria. The value of the metric is modified by calculating the effect of fourteen appropriate adjustment factors. A level of configurability is added by weighting these factors to suit any specific installation. The scores and configuration data are elicited by averaging results obtained from a multi-part survey administered to four or five company employees selected from a wide range of job titles and responsibilities. A simple implementation of the algorithm was completed, and an extension of the work will provide an Internet-based version and a diagnostic tool for company use.

1. INTRODUCTION

Automation projects are expensive and undertaken only after much deliberation especially in the current economic climate. Manufacturing companies increasingly must weigh technological progress against business expediency. Technologically, there are many tools and methodologies available to assist the system designer in the production of a wide range of manufacturing systems. In some cases a new construction project or machinery upgrade requires a corporation to requisition a custom (or packaged) manufacturing information system just in order to operate. Or perhaps the company is being compelled to comply with new regulations, or just seeking increased control over its bottom line. The design and implementation of such appear elsewhere in these proceedings. The author has been involved at both the technical and executive levels in factory systems for many years and his experience has been that few metrics exist that are expressly designed to assess the overall satisfaction of the company and the project success. The literature (for example [1], [2]) reports many project failures that involve IT and technology, and it may be safe to say that most “disasters” elude the media and never reach the public domain other than in court records!

This paper introduces a metric that was designed purely to give a corporation a fair and frank assessment of the success of an automation project across the landscape of the organization. The metric borrows some of the tenets of the Function Point Analysis [3] and Analytical Hierarchy Process [4] methodologies. The paper is organized as follows: Section 2 is a summary of those two methodologies. Section 3 shows the structure of the proposed Automation Metric and includes idealized data from a real factory. Section 4 outlines the data elicitation methodology. Section 5 briefly introduces the software, followed by summary, acknowledgements, and reference sections.

2. SUMMARY OF METHODOLOGIES

The following section summarizes relevant aspects of the Function Point Analysis and Analytical Hierarchical Process methodologies and how some of the features within the methodologies relate to the proposed metric.

2.1 FUNCTION POINT ANALYSIS (FPA)

Function Point Analysis (FPA), created by Alan Albrecht in 1979, has become an ISO standard method of estimating software effort. It is based on producing a function point (FP) count from a detailed analysis of high-level functional requirements documents. Using statistical data from prior projects, FPA can estimate expected levels of effort, such as lines-of-code (LOC) or person-months depending on which implementation language (C, COBOL, etc.) is selected. To begin the process, analysts examine the requirements documents of the proposed system and assign values for the five major categories found in most IT systems - which are:

I. The number of outputs expected in the final system – for example; displays, reports, voltages.
II. The number of inquiries expected in the final system – this includes keyboarding, card swipes.
III. The number of input types – this includes keyboards, sensors, biometric data, scans.
IV. The expected number of files, both permanent and temporary, to be accessed.
V. The number of interfaces the proposed system must make with other systems.

Each value is then divided according to its apparent or expected complexity as simple, average, or complex. For example; if one system interface is into an existing SAP™ implementation, it would be classified as complex, whereas, a keyboard entry requirement would be added to the simple counter etc. Table 1 illustrates the initial phase of the method with data from a fictitious system. In this example, row 3 codifies that the specification has called for 100 inputs, of which 20 are considered simple, 50 are average, and 30 are assessed to be difficult. The application complexity matrix for that category is therefore \{20, 50, 30\} – and so on for all five categories.

Table 1: Application Complexity Matrix ACM

<table>
<thead>
<tr>

<td>IV: FILES</td>
<td>50</td>
<td>10</td>
</tr>
<tr>
<td>5</td>
<td>V: INTERFACES</td>
<td>50</td>
<td>0</td>
</tr>
</tbody>
</table>

Data from prior projects is used to rank the expected difficulty in producing each component in the design. Table 2 shows the typical complexity factor matrix used in many software projects.

Table 2: Complexity Coefficient Matrix CM

<table>
<thead>
<tr>

</tr>
<tr>
<td>5</td>
<td>V: INTERFACES</td>
<td>5</td>
</tr>
</tbody>
</table>

The value of the number of “unadjusted” function points (UFP) is obtained by multiplying ACM by CM and summing terms across the rows which, for this data set, yields a value of 2050. Because of the domain complexities of most systems, this initial estimate is naive and needs to be adjusted to take into account various influence factors [4] for the project as a whole. The actual Function Point count (FP) is calculated by multiplying the Unadjusted Function Point count by a Value Adjustment Factor (VAF). In FPA, the VAF coefficient is calculated from the individual weighting of fourteen factors such as reusability, level of distributed computing, software integration, etc. Because this factor is used in the metric below, it is not discussed in any detail here. The adjusted function point value, \( FP = UFP \times VAF \) can then be used to estimate [4] the project’s expected duration, level-of-effort and the number of lines-of-code in any particular language using a table or graph. For the values given in Table 1, with an example value adjustment factor (VAF) of 1.26, the adjusted FP
value would be re-calculated to 2583. There are several online function point calculator tools [6] available. Figure 1 is a screen capture from http://ivs.cs.uni-magdeburg.de/sw-eng/us/java/fp/. This shows that the estimated level-of-effort for the example project with 2583 function points would be 347 person months. This represents a large project that would require a team of analysts over several years.

![Figure 1: Output from a Function Point Calculator](http://ivs.cs.uni-magdeburg.de/sw-eng/us/java/fp/)

2.2 ANALYTICAL HIERARCHY PROCESS (AHP)

Because most problems have solution options, each one with its own aspects of excellence, complexity, and cost, it is imperative to be able to analytically review and evaluate options based on multiple criteria. The AHP method [6] first establishes a hierarchical scale of goals and sub-goals. Each goal is rated on a scale of 1 to 9, with the value “1” conveying equal importance and “9” indicating a completely more important feature. For example, a design with four goals could be evaluated as shown below in Table 3. The “9” at table position \{2, 3\} indicates that Goal C is very much more important than goal B. For reference, the lower diagonal matrix is just the reciprocal of the upper.

<table>
<thead>
<tr>
<th>Table 3: AHP Level Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>Goal A</td>
</tr>
<tr>
<td>Goal A</td>
</tr>
<tr>
<td>Goal B</td>
</tr>
<tr>
<td>Goal C</td>
</tr>
<tr>
<td>Goal D</td>
</tr>
</tbody>
</table>

The system goals are now sub-divided into criteria which are weighted mathematically using an Eigen vector analysis to obtain the dominant values. Each criterion is assigned a relative weight for each goal, normalized, and multiplied across the level matrix to form composite weights. The criterion with the highest composite figure is an indicator of the preferred option to take in the design. Table 4 shows an example of this where the composite weight of criteria 1 is 0.238 \{=0.507x 0.2 + 0.359x0.3 + 0.094x0.1 + 0.039x0.5 = 0.238\}.

<table>
<thead>
<tr>

<tbody>
<tr>
<td>Weight</td>
</tr>
<tr>
<td>Criteria 1</td>
</tr>
<tr>
<td>Criteria 2</td>
</tr>
<tr>
<td>Criteria 3</td>
</tr>
<tr>
<td>Criteria 4</td>
</tr>
</tbody>
</table>
Table 4 would indicate that criteria 2 is the most significant of the four and is shown shaded. This is by no means intended as a complete description of the AHP method but rather as a simple overview of this decision support methodology, and the interested reader is directed to the literature.

2.3 RELATION TO PROPOSED METRIC

Both of these fairly well known methods provide useful means in the estimation and selection of resources but are both customarily applied before the onset of a project. FPA measures expected complexity and AHP rates viable options based on system variances. The proposed automation metric (AM) described below uses a similar tautology to FPA as indicated by the scoring the various facets of a completed project which are based on the input of actors from within and possibly outside the company. In addition, a weighting and ranking method similar to that found in AHP is used to apply some level of discrimination between factory to factory variations, and to compensate for human inputs across a wide employee spectrum and their corresponding value systems. For example, an operator may value ease-of-operation while an executive might focus more on increased throughput.

3. THE AUTOMATION METRIC (AM)

The proposed metric is designed to give a measure of overall satisfaction for an automation project in a factory setting. The metric is an attempt to objectively evaluate the true worth of an automation project.

3.1 THE UNMODIFIED AUTOMATION METRIC (UAM)

In order to accomplish preliminary data, the so called AM metric utilizes five high-level automation function (AMF) values, each of which is then distributed according to perceived and actual complexity. The essential difference from the FP methodology is that these values are elicited from a survey given to four or five employees ranging in rank from company executive to shop floor operators. The complexity coefficients ($C_k$) are only estimates based on vendor and user opinions. Table 5 contains data that illustrates the calculation of the UAM or unadjusted automation metric.

Table 5: Computation of Unadjusted Automation Metric (UAM)

<table>
<thead>
<tr>
<th>AUTOMATION FUNCTIONS (AMF) – based on responses to a questionnaire with values between 10 and 100.</th>
<th>COMPLEXITY DISTRIBUTION - based on the complexity of the installation – “CM” values</th>
<th>ROW TOTALS</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Row</strong></td>
<td><strong>Data Values</strong></td>
<td><strong>Simple</strong></td>
</tr>
<tr>
<td>1</td>
<td>COST (EFFECTIVENESS) What has been the impact of the automation?</td>
<td>70</td>
</tr>
<tr>
<td>2</td>
<td>OPERATION Do operators find the system easy or hard to use?</td>
<td>85</td>
</tr>
<tr>
<td>3</td>
<td>TECHNOLOGY How does the system rate as far as reliability, accuracy and availability?</td>
<td>80</td>
</tr>
<tr>
<td>4</td>
<td>PRODUCTIVITY Did the automation improve efficiency?</td>
<td>75</td>
</tr>
<tr>
<td>5</td>
<td>INTEGRATION How well does the system work with prior business functions?</td>
<td>65</td>
</tr>
<tr>
<td><strong>UAM TOTAL/MAX</strong></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

For the data given in Table 5, the value of UAM is 2235 out of a maximum possible score of 3700. Taking this as a percentage gives the simplest measure of Satisfaction Level (SL) as ~60% (= 2235/3700*100).
3.2 AUTOMATION ADJUSTMENT FACTORS (AAF)

Because each factory has very different technical performance measures (TPM) and structures, it is again expedient to modify the raw UAM figure using (coincidentally) fourteen Automation Adjustment Factors [AAF] in order to yield a better value. Each item in the table is given a value between 1 and 9 as in AHP. An AAF that performs very well is highly rated and given a score of 9/9, a so-so rating 5/9 and a poor rating of 1/9. Equation 1 is used to limit the VAF influence to ±35% as in FPA – note that the maximum AAF total possible is 126 (=9x14) should all factors be given 9/9.

\[
VAF = 0.65 + 0.70 \times \left( \sum_{i=1,14} \frac{\{AAF_i\}}{126} \right)
\]  

Equation 1

<td>Is the product to be installed elsewhere?</td>
</tr>
<tr>
<td>14</td>
<td>Cost Efficiency</td>
<td>7/9</td>
<td>Has the automation affected the bottom line?</td>
</tr>
</tbody>
</table>

For the data given in Table 6, using Equation 1, the value of VAF is 1.09 (=0.65 + 0.7*80/126). This would then make the adjusted automation point score increase from 2235 to 2436 and seemingly increase the satisfaction percentage from 60% to ~66% ... but this is not so because the maximum possible value of AM is now 4995 (=1.35 * 3700). In actuality, the satisfaction percentage is reduced to ~49% (=2346/4995). Influence factors adjust the automation metric and, therefore, the satisfaction levels to better reflect how satisfied the company is with the results of its automation project.

3.3 CONFIGURATION BY WEIGHTING

In the previous section, the adjustment factors were all considered equally significant in any factory. To incorporate variances in their significance within any particular factory, each adjustment factor is also assigned a weight. This is to avoid an AAF from being over-rated when it is really unimportant. This will further modify the AM value, but not the maximum value attainable as this remains at 1.35. Table 7 is an extension of Table 6 and shows how the company might weight each of the adjustment factors to match their particular installation.

For the data given, the adjustment factor total is now 36.77 out of the new maximum of 70.2 (=9 x 7.8). Using Equation 2, the new value of VAF is 1.01 (= 0.65 + 0.7 * 36.77/70.2), giving a new value of AM of 2257, which in turn translates to a reduced satisfaction level of ~45%.

\[
VAF = 0.65 + 0.70 \times \left( \sum_{i=1,14} \frac{w_i \times \{AAF_i\}}{\sum_{i=1,14} w_i} \right)
\]  

Equation 2

The rationale for this weighting is simple. For example, the AAF6 feature (on line data entry) – shown shaded in Table 6—might work very well as demonstrated by its high score of 7 out of 9, but the company may have subsequently decided to limit data entry on the shop floor and consequently rank this feature as being “neutral” in the rubric shown in Table 7 where item 6 has been assigned a weight of only 0.5. This weighting avoids over-rewarding “something insignificant that works well” as opposed to “something important that works well.” Without such weighting the metric could be skewed upwards by good performance in ancillary features. The data in Table 7 represents a factory with long repetitive job runs and little operator intervention.

4. DATA ELICITATION

In order to populate the tables with meaningful data, a six-part questionnaire was designed. Because data obtained from company personnel (the actors) is qualitative as well as quantitative, careful data collection by an analyst is imperative. For example, assessments proffered by a disgruntled, or soon to be terminated, employee must not be given the same weight as the opinions from more objective sources. Qualitative and quantitative feedback is solicited from staff of varying levels and depths of interface with the factory system. The questionnaire is in six parts with each sub-section contributing to the data in Tables 5, 6, and 7.

4.1 COMPANY AND LEGAL

This section is to be completed by a company executive and may include attachments such as non-disclosure forms and permits. Even though the metric can be configured to be completely anonymous, this proved to be the most difficult part of the questionnaire due to the oftentimes proprietary nature of the production processes at a plant and the reluctance of executives to go on record or to allow employees access to a forum where grievances or illegalities might be aired. Without this buy in, the other parts of the questionnaire are impossible. A common excuse has been that the technical and operational staff does not understand the complexities of capital item purchasing with its own set of tax implications, or the disjoint between equipment and payroll funding. A common complaint is why the millions spent on equipment and systems could not have been used for salary increases.

As an illustration, an extract of Part A of the questionnaire is shown as Table 9.
Table 9: Section of Questionnaire Part A

<table>
<thead>

<td>Probing plans for the Factory of the Future</td>
</tr>
<tr>
<td>A12</td>
<td>Would you like a copy of the final report?</td>
<td>Ascertains reporting paths</td>
</tr>
</tbody>
</table>

4.2 AMF VALUES

The second part of the questionnaire focuses on obtaining overall AMF values and estimating the perceived complexity ratings for each; this part is administered to all interviewees. Data are averaged and the values inserted into Table 6. This yields a broad overview of the company opinions in regard to the success of an automation project and the satisfaction level was calculated, for the given data, to be around 60%.

4.3 ADJUSTMENT FACTORS AND WEIGHTS

This part is used to establish adjustment scores and weights and is administered to all non-executive actors. The averaged values obtained are inserted in Tables 6 and 7. This is a broad overview of the climate in the automation landscape and determines what features of the systems are really important.

4.4 TECHNICAL ISSUES

This part is used to gain insights from the on site IT and Engineering staff who may have installed or integrated the system, or who must now maintain it and who have in-depth knowledge of technical issues. This helps build Tables 5 and 7. The target actors are engineers and consultants, who are always ready and willing to offer opinions!

4.5 OPERATIONS MANAGEMENT

This focuses on local expertise and in-depth knowledge of the mechatronic systems in place by those who must maintain the production line components and resolve schedule and operator issues daily. This relates to the values in Tables 6 and 7.

4.6 PRODUCTION OPERATORS

This part solicits daily occurrences, perceptions, and experiences of the operators and helps build Table 6.

4.7 ADMINISTERING THE QUESTIONNAIRE

Table 10 describes the strategy in regard to which parts of the questionnaire will be administered to which actors. The lowercase “yes” implies that input from that group should not be considered a primary source.

Table 10: Interview Strategy

</tr>
</tbody>
</table>
5 SOFTWARE INTEGRATION WITH THE QUESTIONNAIRE

The AM algorithm was coded into a simple software tool that allows any number of major phyla (AMFs) and any number of weighted adjustment factors (AAFs) to be used. As more AMFs are configured, the metric simply gives larger values to be divided by larger perfect score values. The case tool questionnaire contains anecdotal responses to sets of questions from which numeric data is extracted for processing by the metric. Textual data is simply aggregated into an opinion box for reporting usage.

6 SUMMARY

Project design and evaluation [7] is the bedrock of systems and software engineering. Before the go ahead for any moderately large project is given, it is customary to produce conceptual documents, including as detailed a system specification as is possible before development begins. Tools such as function point analysis and AHP have proved very useful in estimating resources and decisions that must be made in regard to options.

Before a new project can be started it is the author’s opinion that reference to how prior projects were accomplished should be made and especially so before selecting an outside vendor or integrator. Anecdotal and financial references are only partly useful as it is axiomatic that the vendor will provide only the names of satisfied customers. What is needed is a quantitative metric that can provide an unbiased evaluation of completed work. In the manufacturing enterprise, where in-house technical expertise and R&D may be limited, necessary automation projects often mandate the services of an outside vendor, so having data about prior work is essential.

The paper has postulated a simple tool designed to calculate automation points is a measure of automation efficiency and true satisfaction level. The AM method is a metaphor of the Function Point Analysis and Analytical Hierarchy Process methodologies but with major differences. The first is that AM data is obtained in retrospect from completed systems in existing installations. Secondly, input about the usability and acceptance of a system is solicited from the opinions of executives, users, and technical staff to assure a more balanced viewpoint than is possible from system analysts alone. Thirdly, the weighting of adjustment factors attempts to provide a level of configuration in any particular plant. Finally, the AM value obtained for any given site is intended to assess the real worth or value of an automation project to a company.

The project is still active with company visits being planned in several countries of the world. An extension to the project will make the survey Web-based and access to the software granted on a licensing basis. By incorporating some of the qualitative data, it is envisioned that useful “post-mortem” reports can be generated and used as part of a roadmap to improvements in future projects.

ACKNOWLEDGEMENTS

The author acknowledges the contribution of The Pennsylvania State University for its sabbatical support of the project. Some parts of this paper also appear in reference [8] and are included with permission. Materials regarding AHP are taken from a term paper written by, and used with the permission of, Mike Zsilavetz from the Lockheed Martin Corporation who is a (post)graduate student at Penn State Great Valley.

CAN Protocol in diffuse controlling system based on B&R hardware

J. Swider, G. Kost, G. Wszolek, D. Reclik

Institute of Engineering Processes Automation and Integrated Manufacturing Systems, Silesian University of Technology, Gliwice, POLAND

ABSTRACT

The scope of the paper is the description of the distributed control system in B&R Company based on Programmable Logical Controller (PLC) Power Panel 220. The discussed control system includes the Central Processing Unit (CPU) integrated with the touch screen and distributed input and output system. The entire process of data exchange between the CPU of the PLC and the external input-output modules runs along the internal Controlled Area Network (CAN). The distributed control system operated by B&R is a modular solution. The connection of successive input and output modules is possible thanks to the application of the docking station that serves the CAN data rail protocol. Another issue discussed in the paper is the connection of numerically controlled axes to the control system. The addition of a servo-operator is possible by means of the same CAN protocol that is used in the communication between the CPU and the inputs and outputs. The presented solution has multiple large-scale applications involving, for example, the control of 6- and more axis robots, numerical machine tools, process technologies control, remote data acquisition. The paper is substantiated by a real application of the distributed control system implemented in B&R Company in the form of shelves store control.

1. INTRODUCTION

Continuous progress in the fields of industrial electronics and automatic control has contributed to a wide application of advanced technologies of information dispatch in almost all control and adjustment applications [11,……,14]. Network solutions applied in remote collection and dissemination of data have facilitated the expansion of control systems, without the need to use a bigger number of PLCs, as, thanks to the utilization of an industrial network (Profibus, CAN, Ethernet), it is possible to connect the input and output modules to one PLC even if they are located at the distance of several meters away [1, 2, 5, 6].

In the face of wide range of applications (the automotive industry, diagnostics of ships, connections to anti block system (ABS), Electronic Brakeforce Distribution (EBD), etc.), the authors of this paper have decided to utilize the CAN protocol in a distributed control system, in view of its many advantages, which simplify the distributed control of process technologies and ensure a high level of safety. Because the CAN protocol is based on dispatch and receiving messages, controllers and other equipment that transmit the message do not have to know the recipient’s address. As the headline of the message contains the information concerning the addressee, if it arrives to the target unit (often referred to as: CAN node), it will be read out, otherwise, it will be ignored. The solution based on messages rather than addresses makes it possible to receive information simultaneously by many recipients, which increases the speed of information flow in comparison with standard information systems based on sequences through successive network nodes. For example, measurements required for several PLCs may be broadcast by means of the CAN protocol. Thus, the used transmission band is minimized. Another attribute of the CAN protocol limiting the transmission band is called Remote Transmit Request and makes it possible for the system node to send the message through other nodes. Such solution is particularly useful in diagnostic programs. Instead of ordering other stations periodic forwarding of the information on the condition of the system, it is possible to require the information from the nodes that are of lesser importance to its proper operation only if a fault is detected. Another advantage of the CAN main is fault confinement. The main prevents the whole system to be stopped if a problem
occurs only at one node. CAN nodes may perform self-diagnostics and, depending on the gravity of the detected fault (for example: the fault is permanent or temporary) switch to one of the three possible operation manners, including total stoppage. This feature prevents the faulty/damaged node from blocking the communication in the network by continuous notification about the faults, thanks to which the remaining part of the process may run without disturbances [1, 5, 6, 7, and 8].

2. CAN PROTOCOL IN DISTRIBUTED CONTROL SYSTEMS USED IN B&R COMPANY

The CAN solution applied by the authors of the paper was implemented in the subsections of B&R Company, which became an industry leader in innovation and technology and will continue to grow in the coming years and will further strengthen their leading position in the international market.

As the entire project was run on Power Panel 220 controller (with active touch screen) the PLC had to be equipped with the CAN interface to enable the construction of an integrated network structure. Factory made PP220 controllers [4, 5, 6, 7, 8] (also see Fig.1.), do not have the function of serving industrial network, but have an option of adding expansion bus. Such solution enhances the universal nature of PLCs applications, as it is possible to add two cards that extend the operation to industrial networks, including CAN (depending on the type of the controller it may only be one card of network operation). The described project used IF771 card [8, 9] (Fig.1.) for serving the internal CAN with an option of connecting other producers’ nodes (CAN items) by means of CANOPEN protocol emulation [9].

![Fig.1 CAN structure including the added subsections/subsystems. 1. B&R Power Panel 220 PLC, 2- IF771 card for serving CAN, 3- I/O modules docking station of CX470 CAN type, 4- CM211 digital and analogue input-output module, 5- DH439 digital input module, 6- ACOPOS 1016 B&R servo-operator with 8MSA3M engine, 7- expansion bus for servo-operator capacity to include the service of 8AC110.60.2 communication](image)

The PLC equipped in such manner constitutes the first node of an industrial network. As every automatic control system, apart from control units, must also contain operational/executive units, they must be added in the form of the digital and analogue input-output modules to the established one node CAN, as well as the CAN docking stations.
EX470 docking stations (see Fig.1) were used in the project, making up the successive network nodes (NODE#2 and NODE#3). In the next step, CM211 digital and analogue input-output module \[ 6, 8, 9 \] (Fig 1) was connected to the second node, which constituted the docking station. Thus, it was possible to connect the pressure valves and pneumatic valves to the system, and, at the same time, to control the operation of the actuators. As every automatic control system may not be grounded on “trust” in its algorithm, it was necessary to adjoin a proper system of sensors of the position of pneumatic pistons [3] (including the measuring encoder). To achieve this, DI439 digital input modules \[ 8, 9 \] (Fig.1) were connected to nodes 2 and 3 (docking stations) of the constructed CAN. Such configuration facilitated the achievement of the majority of the assumed tasks. Because the necessity of very exact positioning is often one of the major tasks of industrial automatic control systems (as in the case of the discussed application), a numerically controlled axis was also added to the system [3]. The servo-operator used in the project was the B&R one with intelligent ACOPOS 1016 traffic controller [8, 9] (Fig.1). As it was not equipped with the CAN interface, it was necessary to furnish it with 8AC110.60-2 expansion bus [8, 9], (Fig.1). The extended servo-operator, together with the CAN made up another, fourth node of the industrial network (NODE#4). Thus, a functional and autonomous automatic structure was established on the bases of distributed control along the CAN data rail. The layout of all elements of the system is shown in Fig.1. It should be emphasized that the application of a network solution requires every new node to have a constant number, the value of which is designated by two mechanical set-ups (approximate and exact adjustment knob), setting the number in the hexadecimal code (eg. set point 0 and F correspond to number 16) [8, 9].

3. STRUCTURE OF THE KINEMATICAL CHAIN OF HIGH STORAGE MANIPULATOR

The network solution proposed by the authors of this paper constitutes the foundations of the distributed control system which was used for continuous supervision and operational control of high storage. To enable the operation of store indexes involving the collection of details from the production process, forwarding them to the index indicated by the control system, placing them at the right storage indexes and dispatching, upon request, specific products to the collection point, an integrated manipulator with at least 4 degrees of freedom was employed. The following modules are contained in the kinematical chain of the electro-pneumatic manipulator serving the high storage (Fig.2):

- horizontal movement module
- vertical movement module
- gripping arm turn module
- gripping arm reach module
- gripping devices changer together with the devices

Such division is an outcome of the variety of the kinematical couples making up the kinematical chain of the manipulator, as well as of the variety of functions and tasks that they must achieve.

![Fig.2. Diagram of the kinematical chain of a 4-axis electro-pneumatic manipulator for high storage](image)

To drive the horizontal axis integrated with the high storage manipulator, LINTRA M46140/M/25000 bypass piston-free pneumatic servo-operator was used, manufactured by Norgren Herion- see Fig.3.
The piston-free engine was additionally equipped with bracing truck guide bars securing a significant stiffness of the system, improving the accuracy of positioning which is so essential while collecting elements from the store and changing the gripping devices. The horizontal drive is supplied through E/P VP1006BJ101A00 proportional valves produced by Norgren Herion – see Fig.4.

For the measurements of a current position of the horizontal manipulator, Wobit incremental encoder with integrated linear transducer was used, with the measuring capacity of 2500 mm.

In view of the required accuracy of positioning, the vertical axis drive contains M/49132A/BS/052/750 encased cross-helical gear with no clearance manufactured by Norgren Herion. On the bases of the steady operational parameters, the selected drive is B&R 8MSA3M.E0-I6-Rev.D1 controlled by ACOPOS 1016 amplifier shown in Fig.5.

The gripping arm of the manipulator consists of two modules: the reach module and the turn module. The gripping devices changer module is contained in the hand of the manipulator. The gripping arm integrated with the high storage pneumatic manipulator is shown in Fig.6.

The pneumatic servo-operator that turns the arm is M/60272/M/180 Norgren Herion with the operational range of 180°. To secure an option of manipulating the objects placed on the shelves of the store, the gripping arm module is equipped with RM/8021/M/250 pneumatic by-pass piston servo-operator (also produced by Norgren Herion) with the integrated QM/8021 bracing guide bars- see Fig.7.
The gripping arm of the manipulator is also equipped with automatic changer – see Fig.8- constructed on the bases of Norgren Herion mini servo-operator [10], which, by means of an additional element, switches the blockout joint (Norgren Herion).

4. IMPLEMENTATION OF THE OPERATIONAL ALGORITHM FOR THE CONTROL SYSTEM BASED ON B&R DISTRIBUTED SYSTEM

The first step made in the course of creating a parametric program that controls the operation of high storage was the configuration of the equipment. Accordingly, a new project was set up in B&R’s Automation Studio software environment, and, first and foremost, a decision undertaken concerning an applicable type of PLC. The selected PLC is PP220.1505-B5. The Automation Studio, on the grounds of the chosen PLC type, selected the right version of the operational system. Once the configuration of the basic project was finished, it was possible to move on to the main screen of the environment- see Fig.10.
In the left part of the screen there is a hardware configuration tree. The right part of the screen contains detailed characteristics of the object indicated by the tree. Due to the indication of the master object in the form specifying the name of PLC, the right part of the screen displays a tree of the installed components (libraries, visualization objects and program tasks). To introduce the controller of servo-operator ACOPOS 1016 to the hardware tree, as well as the analogue and digital input and output modules, it was necessary to define the expansion bus to be installed in the PLC and other successive components connected to CPU through CAN. After defining the docking stations and the input and output modules, in the fourth node of the network the controller of ACOPOS servo-operator was defined and an engine cooperating with the servo-operator (object 8V1016.50.2).

Upon forwarding the created project to the PLC it was possible to start-up the environment testing the servo-operators. The test mode enables the assumption of control over the operation of the servo-operator by ON-LINE computer, thus, the action of the PLC is replaced by the servo-operator. In the course of starting up the vertical axis drive of the pneumatic manipulator which is integrated with the high store, the “Test” environment was used by designating the optimal values of the displacement and velocity errors reinforcement coefficients. The left upper part of the test module screen (Fig.11) shows a set of instructions contained in the operational structure of the numerically controlled axis. The instructions available in the window (1) may be extended by other ones accessible from the programming language level.

In the right lower part of the screen (2) the parameters of the states of the servo-operators are displayed (structure “p_ax_dat.monitor). Above the instruction screen (1) there is a signal of the readiness of the servo-operator and the emergency STOP button for the servo-operator engine. Above the states readouts (2) there is a signal of the engine supply, turning on the positioning adjustment, states readouts, drives and servo-amplifier errors sensor. In the central part of the screen there is an access window to the servo-drive structure (3), and, at its right side (3) the editor of the parameters values concerning the selected substructure (4). To facilitate the tracking of the parameters values, the oscilloscope window is displayed at the bottom of the screen (5). In view of a specific nature of single-phase B&R drives, it was necessary to switch off the standard monitor of the three-phase drive and to introduce a default change of the effective value of the supply servo-amplifier. To change the default parameters the service channel is used. The service instructions are sent in three stages. First of all, the number of the service instruction should be set-up. After that, a new value of the substructure entered (data_tex). The execution of these activities results in a new value of an indicated service parameter to be saved in the buffer. The change of the service set-ups shall be active until the Test environment is abandoned.

The initiation of the procedure of adjusting the servo operator entails the change of the velocity error reinforcement coefficient. In the first phase of the adjustment (loading the engine shaft), this coefficient kv =0. The
adjustment of the displacement error requires the start-up of the servo-drive and tracking the displacement variable and the velocity. The adjustment of the displacement reinforcement coefficient involves a gradual increase of the value of kv, until self-excited vibrations of the engine shaft appear, so the final value of kv was assumed 12. This value is a safe boundary value of the coefficient, above which considerable increase in the velocity oscillations are observed. After the adjustment procedure for the displacement reinforcement coefficient is finished, the velocity control parameters are adjusted, on the grounds of the proportional dependence between the moment and the current intensity in the engine winding and by means of Fourier transform (FFT) which is available as an embedded function in the Automation Studio environment.

5. SUMMARY

The CAN solution utilized by the authors of the paper constitutes a perfect example of a distributed control system. A single B &R PLC used in the system enables the connection of 255 nodes of basic CAN, so the control system may be extended to a very large degree. Such solution may provide simultaneous, safe and functional control of many different subsystems of industrial automation. Thus, it may be concluded that such solution used for big applications enables the elimination of a significant number of logical PLCs in favour of just one controller with the implemented CAN service, leading to the reduction of the costs of the control system of the entire application, and improved clarity of connections (cabling), with the parallel easiness in identifying the input and output signals. The use of distributed control also makes it possible to avoid measurement errors caused by the drop in the measured voltage values (analogue measurements) along the signal wires, if the module with the A/C converter is placed in the nearest vicinity of the object, the voltage signal of which is to be measured. The information sent to the master PLC is converted into a digital form, which is not sensitive to the phenomenon of voltage drop (while preserving the required network span- as recommended by the manufacturer).

Abstract

A CCD based vision sensor system is described in this study. Such a vision system offers both the color images from the object under study and also provides quantitative information concerning the image intensity profile. It is possible to obtain reflection and image data by using single or double light sources for the object illumination. Using the active and passive lighting combination, the reflection data and image profile for different fruits are obtained and presented in this study. To check the potential of the reported vision system for fruit grading and shape analysis some of the related data is described here. The image intensity profile as a function of the x and y coordinates are obtained from fruit surfaces such as banana (plain surface) and apple surface (spherical). The observed intensity profile for the plane surface is uniform in both x and y directions while the spherical surface shows a maximum value at a particular x and y values. In another study the reflected light from fruit surfaces are collected by using a laser light source. Reflected intensity depends on the light wavelength, surface color and its characteristics, which can be helpful in vision analysis. Proposed method can be implemented effectively in the fruit production line for color and shape/size grading purposes.

1. INTRODUCTION

Expected functions from a machine vision system are the capturing of images, analysis of those captured images, recognition of certain objects and features within each image, and the initiation of subsequent actions in order to accept or reject the corresponding objects. Vision system stages are image acquisition, pre-processing of image, segmentation, feature extraction, classification, inspection, and finally actuation which is an interaction with the scene under study. Vision system developments in manufacturing can result in improvements in the reliability, in the product quality and enabling technology for a new production process [1]. Operation of a vision system starts with the image acquiring in which image sensing, digitization, and representation of the image data are accomplished. Scene constraint is the main consideration for the machine vision system and the situation of the scene must be recognized by the machine vision designer. Thus according to the required application needs an appropriate machine vision system should be developed. The hardware for this system consists of the light source for the active imaging and required electro-optical and opto-mechanical sub-systems.

Different lighting techniques such as structured lighting can be used for scene illumination. One possible development in the area of vision hardware system is using the laser scanning systems. To acquire 3-D information one can use a bi-dimensional scanning method as described in Ref. [2]. Another possibility is to use x-ray or infrared lighting, which offers some advantages. For example machine vision and infrared lighting technique has been used to track production quantities, detect defects, and screening problems. The infrared spotlight is employed to detect and inspect glass-bottle flaws [3]. X-ray technology machine vision system has been proposed for the inspection of the air-bag inflators. High quality machine vision system should integrate an image acquisition subsystem that produces a high resolution pictures (512x512 pixels). Such devices offer significant advantage to acquire precise information about relative positions of several objects within a scene in a single glance. Design of industrial machine vision...

systems for automated manufacturing and the role of laser lights were presented in our recent reports [4-7].

2. VISION SYSTEM DESIGN

Block diagram of a typical vision system is shown in Fig.1. As can be seen it includes a light source illuminating on the object under study, an image CCD camera, the interface card for the camera, and a PC. The output of camera is connected via an interface board to a PC and signal processing and camera control is accomplished by using related software [1]. Several tasks such as image acquisition, processing, segmentation, and pattern recognition are conceivable using machine vision system. In recent years a new field of applications in sensing area has opened up and using such fibers a variety of optical sensors have been reported as physical and chemical sensors. The goal has been here to implement such fiber design in the construction of vision sensors/systems.

As can be seen in Fig.1, it includes two light sources illuminating on the object under study via a dual fiber design and direct illumination, a CCD camera, the interface card for the camera, a PIN photodetector, a digital multimeter, and a PC. In the double fiber design one fiber is used for the illumination of the object and the second one is used for the transmission of the reflected light from the object to the digital multimeter. A silicon photodiode (BPX 65 Centronic) is used for light detection and conversion of optical signal to an electric one. The electric output signal of this detector is connected to a digital voltmeter by a coaxial cable. A digital multimeter (SANWA Electronic Instrument Co. LTD, PC 5000 DMM) is used for the output voltage reading and data processing (±0.1mV precision). This device equips with an optical isolated interface port at the meter back for data communication with a PC. The software (PC Link plus) allows one to log measuring data into a PC through RS232 port. The operation of this software is possible by using any operation system such as windows 98, NT4.0/2000/ME/XP versions.

The output of CCD camera is connected via an interface board to a PC and signal processing and camera control is accomplished by using related software. The CCD camera is a miniature camera (34×34 mm size, model TBC-312C, TÉVICOM). It is a camera with alternate lens configuration (flat pin-hole, Con type pin-hole lens) 1/4 inch color interlines transfer CCD, built in microphone, extremely low power consumption, and high quality image. Other specification of this camera is a scanning system (2-1 interlace 625 Lines/50 Fields, 25 Frames), effective pixels 510(H) × 491(V), resolution of 380 TV Lines, illumination minimum of 0.8 LUX, S/N ratio >48 dB. Video output 1 V p-p 75 ohm, VBS, with auto white balance, background compensation and internal synchronization. It has an electronic shutter 1/60-1/100000, lens regular, flat pin-hole, Con pin-hole lens. Power source requirement is 12 VDC and 200 mA with a power consumption of 4.5 W. The used lens option is Con-pin-hole lens (F2.0:f3.6) type that its selection depends on the application requirements [8].
The CCD camera operates with the DVD maker USB2.0 hardware and PVR PLUS software (KWORLD) that operates under all the Microsoft Windows operating systems. The DVD maker USB2.0 hardware requires a Pentium-IV 1.6GHz or higher speed type, 256MB RAM of system memory or above, a free USB port, Graphic card, CD-ROM drive, and needs 1GB of free HD space. After the drivers are installed, the next step is to install the PVR PLUS software. The software functions are the TVR: this function turns the computer PC into a full-featured video recorder. MPEG Encoder: MPEG encoder converts AVI files into MPEG format. Video Editor: makes editing MPEG video files easy. Function Burns DVD: burn DVD creates VCD, SVCD and DVD that can be played on a PC or DVD player. The output of the CCD camera is a PGM file type, which is often hard to be processed by the regular programs. In this experiment arrangement is made to convert the portable graphical (PGM) files to MATLAB files, which can be easily manipulated by the MATLAB or EXCEL program. A typical matrix dimension of 240 rows by 320 columns is provided in which the pixel data of the camera are stored.

It is possible to use the coherent and non-coherent light sources for the object illumination. A with lamp operating under 20-25 V dc voltage is used in this experiment. By variation of the supply voltage, it is possible to change the brightness of the light source. Typically a voltage of about 25 V is used in the results reported here. However it is important to have a similar source light intensity for illuminating all the objects under study. Otherwise the obtained results can not be compared together without the required normalization. One of the important design parameter in developing a machine vision system is the most effective type of lighting, which depends on the light source and the related optics. Now system integrators can select from a number of illumination technology such as fiber optics, tungsten lamps, fluorescent, and light emitting diodes in a number of possible configurations. These configurations in clude ring light, spotlight, backlight, and diffuse light. Light sources are able to enhance imaging contrast. Proper light source helps discern imaging features for machine-vision systems. The reflectance light measurement is used for the simultaneous monitoring of both reflected and transmitted lights. Even though the reflectance image could also be monitored by a similar CCD camera, but in this case we used a photodiode arrangement to record the reflected intensity of the light from the objects under study. More information concerning design and applications of vision system are given in Refs. [9-12].

3. Experimental Results

For data acquisition, the MATLAB program is executed in which different subprograms and parameters concerning the data acquisition, and the characteristics of the image are entered as input. By running this program the picture taking begins by the camera while the recording time depends on the camera speed and the number of frames captured. The goal here has been to get simultaneous reflective and transmittance information from the object under study. In the first experiments only light source 1 is used in Fig.1. The aim here is to find a transmitted image signal for the test samples illuminated by the white light source. Furthermore it is desired to have stored image data for further analysis. The combination of the live image and the stored one can results in a true picture of the object under study, which is the ultimate goal of any ideal vision system. Considering this point in this study the live image and its corresponding stored data are recorded. Since there are many images and data only typical examples are described in this report. In order to cut the effect of the room light in the reflection measurements a black cover is prepared for the experimental set up. In this case the room light is also off and the corresponding image signal is due to the dark noise generated by the CCD camera.

A low noise CCD usually offers a lower background noise signal. A white light source and the photo-electronic detections the ratio of the signal to ratio (S/N) is the defining factor for the signal detection. In order to increase this ratio the signal level should be increased and the equivalent noise signal must be reduced as much as possible. However, in increasing the signal level one must avoid the saturation of the photo-detectors. In this experiment care was taken not to saturate the CCD camera photo-sensors. For this reason the lower light intensity was used for the picture taking and image construction. In data representation the capture program normalizes the image intensity to one and care was taken to record intensities lower than one to avoid the detector saturation.

3.1 SHAPE GRADING

To check the potentials of the reported vision system for grading and size analysis some of the related preliminary data are presented in this section. Fig. 2 displays an intensity profile from the taken image for the yellow banana using a white light source. The intensity profile as a function of x is shown in the Fig.2. As can be seen in Fig.2, a uniform intensity is resulted for such a scan since the banana skin is almost uniform in dimension through the scanned distance of about 6 mm. A similar investigation is performed for the y direction and the results are shown in Fig.3. Similar to
the x direction a uniform intensity profile is obtained from the banana skin in the given direction. It was noticed that for the fruits with a planar surface the intensity profile is nearly uniform as indicated in Fig. 2 and Fig. 3.

![Figure 2: Intensity profile for the banana skin in the x-direction](image)

![Figure 3: Intensity profile for the banana skin in the y-direction](image)

Similar studies are performed for the apple with the spherical surface profile. Fig. 4 displays an intensity profile from the taken image for the red apple using a white light source. The intensity profile as a function of x is shown in the
Fig. 4. As can be seen in Fig. 4, the observed intensity shows a maximum value (58 mV) at x value of about zero. From this point as can be seen in Fig. 4, the intensity decreases in an exponential way to reach a value of about 50 mV as shown in Fig. 4. A similar investigation is performed for the y direction and the results are presented in Fig. 5. Similar to the x direction, an intensity profile is maximum of about 57 mV at a y-value of about zero and reach to a value of about 48 mV at y=3.5 mm.

**Figure 4:** Intensity profile for the reflection from apple skin in the x-direction

**Figure 5:** Intensity profile for the reflection from apple skin in the y-direction
3.2 COLOR GRADING

In order to test the potential of the reported vision for color grading some of the related preliminary data are presented. The sample tests for this study are the fruits with different colors. As can be seen, the reflection data is very sensitive to the surface material and color that can be used for color recognition and grading of different fruits and agricultural products. Such study also can provide some information concerning the skin properties of the fruits or other products. However, more details about such applications require more experiments in this field that is one of our future goals for the reported design. Of course, some modification is required in order to fit the reported system for any particular application depending on the application requirements. Such modification can be in the area of light illumination and sensing images.

In the next study, reflection and image data resulting from real-size fruits are presented. Fig. 6 shows the real-time CCD images of different fruits at a similar condition.

Figure 6: CCD images of different fruits. (a) green apple room light off, (b) green apple, (c) yellow plum, and (d) orange nectarine
In order to get some information from reflection in Fig. 7 reflection signals for different fruit samples are shown. As we know the reflected light depends on the light and surface characteristics. In Fig. 7, since the structure and the reflectivity is different from one type to another one; therefore it is hard to contribute the signal difference to only the fruit color surface.

4. CONCLUDING REMARKS

A general-purpose machine vision system with its preliminary applications was described here. Design and operation of the reported vision system is based on the combination of the room light and a source light. By using both the reflection and image intensity profile techniques data for the object under study are obtained and analyzed. Using this system it is possible to obtain the real-time image of the object under study or store the image data in a matrix for the further processing. In real-time analysis it is possible to look at different processes and display images in different formats. In post-processing it is possible to average image signals from different shots, look at the background signal and correct the resulting image signals for the background corrections.

Object identification and classification are one of the most important applications of a vision system. Applying reported vision system can be helpful in the analysis of small objects and monitoring production processes. It also provides on-line inpection possibility and imaging options for fruits and packing in automotive production assembly lines. Sorting of parts, identifying and unloading of parts from pallets are important applications. Sorting and grading of food and other products are an other example of such identification applications. A list of possible applications of the vision system with more details can be found in literature [13-17].
The next generation vision system should implement laser source light, in particular semiconductor lasers, in order to improve the quality of the captured images. The next generation should lead towards machine vision systems with the universal capabilities to provide 3-D description of the scene. In the design and operation of a vision system, image formation and visual processing, computational methods and algorithms, depth information, image representation, and modeling and matching must be considered. On the other hand, systematic consideration is important in the efficiency and performance of the selected machine. Integration possibility, robustness, ease of operation, and adding intelligence into the system in order to make it a smart system are features of an advanced machine vision system.

Feasibility of an AIDC System within a Manufacturing SME

Sara Zarei*, Simon Hodgson and Farhad Nabhani

School of Science and Technology
University of Teesside
Middlesbrough, TS1 3BA, UK

ABSTRACT

Automatic Identification and Data Collection (AIDC) Systems have been widely used within the manufacturing industry to allow information to pass easily and accurately between different stages of the supply chain. AIDC technologies can be categorised as Biometrics or Data Carrier technologies; Biometrics include fingerprint recognition technologies, facial recognition and voice recognition whereas Data Carrier consists of optical, magnetic or electronic storage. AIDC systems utilising Data Carrier technologies have been successfully implemented within many large multinational organisations but research into the implementation of AIDC systems within SMEs is far more limited.

The processes and operations conducted at a manufacturing SME located in the North East of England were critically analysed and explored in order to identify areas where lean manufacturing principles can be implemented and also areas where the use of an AIDC system could be used to improve the efficiency and visibility of the processes throughout manufacture. Process activity charts were produced for each of the processes at the company to include the operations and transfer times for analysis. This provided a systematic approach for the analysis of current processes and for determining the cost benefits based on the identification and reduction of non-value added operations in the process. The areas for improvement could then be identified and solved through specific applications and/or systems of which a cost benefit analysis could be conducted. The feasibility of the implementation of an AIDC system and the recommended modifications to the shop floor layout were then discussed to determine the benefits available through the recommendations made.

1.0 INTRODUCTION

The case study will be conducted at a Small to Medium Enterprise (SME) located in Middlesbrough, in the North East of England that specialise in the manufacture and refurbishment of feedscrews and barrels for the plastic, rubber and food industries and also provide expertise in welding and hardfacing for the vessel and nuclear industries. [1, 2] The company manufacture parts as required through a specific customer order, known as job shop manufacturing, which provides a high level of customer support and interaction.

In the manufacturing industry, the tracking of a product and its status through the processes of a company, from the moment it arrives until the time of despatch, can significantly reduce the lead time, increase the efficiency and visibility, increase the accuracy of production plans and also improve the efficiency of an ERP system. As the constant demand for total visibility and fast and accurate information flow increases, the inefficiencies of traditional systems are becoming more apparent. [3]

This paper aims to educate and assist organisations with the selection process of AIDC technologies within a Small to medium size manufacturing organisation. A process mapping exercise is conducted to investigate areas that may benefit from an automatic identification system and the improvements that could be made. A method of assessing the cost benefits of an RFID system application is also covered as this is considered the major barrier for the implementation of AIDC systems within SMEs. This study aims to establish a methodology that may be used by many organisations in order to investigate areas of improvement within a process that may benefit from the implementation of such a system.
2.0 Automatic Identification and Data Collection Systems

Automatic Identification and Data Capture (AIDC) technologies and systems were initially developed as a response for the requirement to collect and transfer levels of data in an efficient, quick and accurate manner. AIDC technologies have since developed immensely and may now be used for many purposes in a number of industries. AIDC technologies can reduce or even eliminate the occurrence of errors in the collection of data and the manual input or entry of data and has been successfully applied in the retail, logistics and manufacturing industries. AIDC technologies are distinguished in two separate groups; biometrics, or feature extraction, and data carrier technologies as shown in Figure 1 [3 – 5]

![Figure 1 – AIDC Technologies](image)

Biometric or feature extraction technologies are AIDC technologies that measure physical and behavioural characteristics by exploiting object, action or property relations. The most widely used feature extraction technologies include fingerprint recognition, facial recognition and voice recognition but technologies such as iris and retinal scanning are becoming more popular with the increased technological capabilities. Data Carrier technologies encode and decode information through three separate means; optical storage technologies, magnetic storage technologies and electronic storage technologies. [3, 6-7]

2.1 Optical Storage

Linear Barcodes - The most widely used AIDC technology is linear barcodes which are predominantly used in the retail industry and can be found on almost all commercially available products as the technology is easy to implement and has a low installation cost. Linear barcodes have also found applications in manufacturing support systems such as inventory control, tool control, shipping and transportation. The barcodes encode data via width or height modulated lines and spaces that are of a parallel arrangement and data may only be encoded in one direction. Width modulated barcodes encode the data through the variation in the widths of the lines and spaces present, whereas height modulated barcodes encode the data through the variation in the height of the lines. The size of the barcode utilised is dependant on the amount of data that it is required to carry; the more data required, the larger or longer the barcode. [3][4][8]

2D Barcodes – The limitations of linear barcodes, with respect to the amount of data they can carry and their size, have made them inadequate for some applications as they do not have the capability to carry the level of data required in the traceability applications required in industries such as the automotive, aerospace and pharmaceutical industry. Large volumes of data are necessary to be encoded, sometimes in size limiting spaces, in order to keep track of manufactured parts, assembled parts, supplier information and batch and cost information. The requirement to carry this large amount of data and the often limited space available has led to the development of 2D. [3][5][8]

Optical Character Recognition - OCR is the use of a scanning device to identify a printed text through a computer system. The use of certain fonts, such as OCR-A and OCR-B, comprising of numbers 0-9, letters A-Z and a limited number of characters are the means of information transfer. OCR technologies have currently had very little impact on traditional AIDC applications due to their previously high costs and limitations in recognition algorithms. [3][9]
2.2 Magnetic Storage

Magnetic stripes are the second most widely used AIDC technology as they are often seen in credit/debit cards, railway tickets and identification cards. This technology encodes the data onto a magnetic stripe, which is made from many small magnetic particles bound together in a resin based compound, and can be applied to any non-magnetic surface material. There are three tracks contained within the magnetic stripes onto which the data may be encoded; the characteristics of these tracks, their functional usage and their position have a pre-defined standard. The density of the bits on each track dictates the amount of information that can be encoded onto it, also taking into account the format of the data. [3][4]

2.3 Electronic Storage

Smart Cards - A portable device which can be used to automatically identify items, transaction and events is known as a smart card. The smart card must have a storage memory, a chip operating system memory, a central processing unit in the form of an integrated circuit chip and a read/write interface in order to function correctly. The data required is stored in the chip operating system memory and then may be accessed for various processing applications. [3]

Radio Frequency Identification (RFID) - Radio Frequency Identification (RFID) is an AIDC technology that is used to identify people or objects carrying encoded microchips through the use of radio waves. RFID technologies were initially developed by the British military in the 1940s in order to be able to distinguish their own aircraft from the enemy aircraft which was performed by equipping the aircraft with devices to send out coded signals in order to identify them as their own. RFID technologies have since found applications in many everyday devices such as remote controls for gates or garage doors, anti theft devices in vehicles, security systems and the new European Union passports. [3][10-11]

3.0 Methodology

In order to determine and sustain areas of improvement within a company, the processes and operations currently in use must be understood and analysed in depth. Process mapping is a visual approach that is used to observe, understand and question each step of the process while analysing any potential areas for improvement. Each step of the process is identified, described in terms of how they relate to one another and all influencing factors are identified. These influencing factors include inputs into the process, outputs of the process, people involved in the process, time taken to complete the process, the quality of the parts produced and the working conditions involved. [12 – 13] There are many different approaches that may be used to conduct a process mapping exercise; however, they all have the same major features. All process mapping approaches aim to identify the different types of activity that take place during the process and illustrate the flow of materials, people and information through the process. [12]

A process chart, or process activity map, can be used to show the sequence of operations or activities involved in the process from beginning to end with the duration of each activity included. A process activity map analyses each operation of the process as well as any delays, transportation time and inspection stages throughout with the aim of distinguishing between different steps in the process and categorising them as an operation, transportation, inspection, delay or storage activity. Using a process activity map, it is also possible to critically analyse and distinguish between the value adding and non-value adding operations for a more detailed evaluation of the process. A value adding operation is an activity that directly adds value to the end part or process as it is something that the customer is willing to pay for, whereas a non-value adding operation is any activity that does not directly add value to the end part or process as the customer will not pay extra for this operation in particular. Non-value adding operations should be attempted to be eliminated from the process, however, they can sometimes be an operation which must be performed for the process to flow but does not directly add value to the process. Such operations cannot be fully eliminated from the process as they are required for the successful completion of the process. Once an accurate process map is complete, an analysis can take place and any areas for improvement can be identified and suggested in an attempt to eliminate any bottlenecks in the system or idle times which would affect the efficiency and productivity. [12]

Due to the fact that the SME studied manufacture on a specialist and precision level specifically to the order of a customer, known as job shop manufacturing, they do not follow a specific sequence of processes for every job. As each job is different, the process mapping exercise for the company became very complex. In order to conduct the process mapping exercise, an example job of each type of product manufactured or refurbished at the company was examined to give an indication of the typical stages followed throughout each process. Upon analysing each stage of
the process for an example of every product manufactured; it became apparent that the flow of materials, people and communications across the shop floor was extremely erratic and disorganised. In order to investigate the flow across the shop floor at a more critical level, a plan of the shop floor was gained and the movements of all stages followed were mapped out. This method allowed a visible interpretation of the transportation steps throughout the company prior to the analysis of the processes themselves.

Once the current state process mapping exercise was completed accurately, the current state of each process was analysed in order to distinguish any bottlenecks and/or wasteful activities that may be eliminated or reduced through the application of an Automatic Identification and Data Collection (AIDC) system. The duration of each stage of the process was also established along with the type of activity documented which allowed for a critical analysis prior to comparison between the current state and modified state of the process. The various steps in the current state process mapping exercise were analysed by following each stage of the process as it took place through direct observation, collecting the data directly from the shop floor and discussing the process with workforce involved. The layout of the shop floor was also identified as a major problem when observing the operations and stages of each process. The positioning of machinery, stores and work bays did not seem to appropriately facilitate the manufacturing process for any of the jobs followed which caused a large amount of wasted time and resources in transportation manoeuvres.

The potential areas where improvements could be made were highlighted by identifying and eliminating the non value adding operations such as manual input of data and manual creation of vast amounts of paperwork. The transportation times were also attempted to be reduced through the alteration of the shop floor layout by improving the visibility, communication and positioning of machinery and work bays. The implementation of a suitable AIDC system was investigated as a method of eliminating the extensive level of paperwork and the transportation of this paperwork from one stage to another throughout the process. The main requirements of the AIDC system were to increase process efficiency, be applicable to the metallic surfaces of the products, utilise handheld portable devices for use on the shop floor and also be user friendly with a minimum amount of training required. The AIDC system aims to replace a various number of manual steps that are currently in place at the company and also increase the visibility and communications between each stage of the process in order to reduce the lead time of a product. The implementation of an AIDC system within the company has the ability to reduce the amount of wasted time throughout the process, reduce the quantity of paperwork and physical inputs required and reduce the level of inventory required whilst also increasing the communication and visibility of parts across the shop floor with the aid of a modified layout. However, in order to establish the actual benefits of the implementation of an AIDC system and the alteration of the shop floor layout, a cost benefit analysis must be performed to establish the savings that could be achieved with such an investment.

### 4.0 RESULTS

#### 4.1 PROCESS MAPPING

The layout of the shop floor at the SME was identified as a problem due to the poor visibility and communication between the stages and also the lengthy transfer times. Due to the fact that the company is split into two separate workshops and each individual stage requires the part to be frequently moved from one to the other, the transfer times throughout the process were high. The design of the shop floor was therefore modified in an attempt to facilitate the processes as best as possible without compromising one for another. The layout was modified so as each stage of the manufacturing process follows the previous in a U-shaped manner across the factory floor from beginning to end; however, even after modifications were made, not all of the process could follow an exact U-shaped production line. The processes were re-mapped for the modified shop floor layout in order to analyse the future flow of materials and information. As the company manufacture parts to a specific customer order, the process stages followed for each job are different, making it impossible to have an exact U-shaped production line for every process. The modified shop floor plan was designed to be the best possible compromise for each of the jobs followed in order to improve the visibility, communication and efficiency throughout the process. Figure 2 shows the current shop floor plan with the flow of processes for one job and Figure 3 shows the modified shop floor layout with the flow of processes for the same job.
The current state process activity map was analysed and each individual operation was considered alongside the benefits that may be felt through the implementation of an AIDC system and the modification of the shop floor layout. The processes were then simplified to become more efficient and reduce any unnecessary stages. The duration of each operation was also critically considered for the areas in which increased visibility and communications through the use of an AIDC system were identified and improved. The reduction in the transfer times between the stages through the modified shop floor layout was also considered in the process activity charts and was adjusted accordingly. The modified state process activity maps could then be created with any unnecessary non-value adding activities eliminated alongside any avoidable delays and lengthy transfer times. Figure 4 shows the differences between the current and modified process maps with the elimination of any delays and lengthy transfer times due to increased communication and visibility through the implementation of an AIDC system and the time reduction in physical transfer time between stages due to the modified shop floor layout.
4.2 COST BENEFIT ANALYSIS

Once the process mapping exercise was conducted for the current and visualised state of the manufacturing process for an example of each product, a cost saving analysis can be carried out to assess the potential savings to be made. In order to analyse the savings as accurately as possible the figures for inventory levels, safety stock and sales figures were gained from the company.

The level of safety stock could be significantly reduced through the implementation of an AIDC system within the company. [14] Using the information and data collected from the company, the estimated savings per year from the reduction of inventory levels through the implementation of such a system are shown in equation (1)

\[
\text{Savings} = (\text{Total Inventory Value} \times \text{Carrying Cost} \%) \times (\text{Safety Stock} \%) \times (50\%) \\
= (£130,000) \times (10\%) \times (50\%)
\]

\[
= £6,500
\]

The cost of manual counting and tracking times can be reduced by 80% through the implementation of an AIDC system. [14] The manual tracking of the jobs across the shop floor was completed on a weekly basis and took 5 hours in total to complete, including the manual input of the results; this also proved insufficient as real time job tracking is required. The estimated savings per year for the elimination of manual tracking is shown in equation (2)

\[
\text{Savings} = (\text{No. of counts}) \times (\text{Time taken per count}) \times (\text{Hourly labour cost}) \times (80\%) \\
= (52) \times (5) \times (10) \times (80\%)
\]

\[
= £2,080
\]

Improvements in process efficiency through the implementation of an AIDC system can also be calculated through the process mapping exercise. The amount of hours saved for each process was gained through the comparison of the modified process activity charts and the current process activity charts. Table 1 illustrates the total annual savings that can be seen through the implementation of a suitable AIDC system at the company. The savings for each process are calculated using equation (3).
Savings = Process duration x Parts per process x Hourly labour cost

\begin{align*}
\text{Table 1 – Cost Benefits for Each Process} \\
\begin{array}{|l|c|c|c|}
\hline
& \text{Hours saved per} & \text{Cost savings per} & \text{Cost savings per year} \\
& \text{process} & \text{process (£)} & \text{ (£)} \\
\hline
\text{New Screw} & 8 & (8) x (1) x (10) = 80 & (80) x (300) = 24,000 \\
\text{New Barrel} & 3 & (3) x (1) x (10) = 30 & (30) x (150) = 4,500 \\
\text{New Feed Liner} & 6.25 & (6.25) x (1) x (10) = 62.5 & (60) x (80) = 5,000 \\
\text{Tie Bar} & 7.75 & (7.75) x (1) x (10) = 77.5 & (77.5) x (50) = 3,875 \\
\text{Screw Refurbishment} & 5.5 & (5.5) x (1) x (10) = 55 & (55) x (350) = 19,250 \\
\text{Barrel Refurbishment} & 4 & (4) x (1) x (10) = 40 & (40) x (50) = 2,000 \\
\hline
\text{TOTAL} & & & \text{£58,625} \\
\end{array}
\end{align*}

Table 2 illustrates the total annual savings that can be considered for this case study through the implementation of a suitable AIDC system for inventory, tracking and process efficiency.

\begin{align*}
\text{Table 2 – Total Annual Savings} \\
\begin{array}{|l|c|}
\hline
\text{Savings} & \text{Amount (£)} \\
\hline
\text{Inventory Savings} & \text{£6,500} \\
\text{Manual Tracking Savings} & \text{£2,080} \\
\text{Process Efficiency Savings} & \text{£58,625} \\
\text{Total Annual Savings} & \text{£67,205} \\
\hline
\end{array}
\end{align*}

4.3 **AIDC System Design**

The level of data required for each part at the company would mean that the linear barcode used would have to be a minimum of 1.5cm high and 9.5cm wide in order to contain it all. [15] They are also easily damaged through scratches and dirt, and therefore were deemed unsuitable for application on to the metal surfaces of the products at the company.

2D barcodes applied to the product in the form of Direct Part Marking (DPM), by permanently engraving the code onto the part, were examined. Data Matrix is found to be the most appropriate method of DPM for use as job tracking as the information encoded may be read even when it has suffered up to 40% damage and would also required a much smaller space than linear barcodes, at about 1cm high and 1cm wide. [15] The quality and durability of the mark is affected by the material into which it is engraved and the environments to which it is exposed. The harsh manufacturing environments of the products at the company would mean that the mark could easily be damaged through the turning, milling and grinding stages of the process.

Externally applied passive RFID tags were unsuitable for use within the SME as the presence of the tag externally would compromise the performance of the process and the functionally of the part itself. Upon a comparison of the AIDC technologies, glass type tags were found to be the most suitable as they could be embedded into the parts with minimal machining and are small enough to be discreet and not interfere with the manufacturing or performance of the part. [16-18] The glass tags come in a variety of sizes, ranging from 12mm to 32mm in length which makes them versatile for parts of all sizes and allows for minimum machining for the application of the tag. An RFID tag would have to be embedded into the body of the product at the company to protect from damage and allow the product to function properly. The metal surfaces of the parts could cause a problem for RFID technologies, as the metallic surfaces can interfere with the signals used to read the tag; however, it was found that the use of an adhesive resin to position the tag within the part would provide protection for the tag and also a barrier layer between the tag and the metal surface which would allow for the data to be read without any interference.

The main restraint for any AIDC system at this company would be the temperature extremities as the screw flights are heated to temperatures of a maximum of 200°C during the plasma hardfacing process and so the tag would be required to be positioned in a different place for this part. If the technology applied is required to be present on the product throughout its lifecycle in the event of refurbishment being required then it can be subjected...
to temperatures ranging between 110°C and 320°C in use. However, there are areas on each product that are not subjected to these extreme temperatures, such as the drive of the screw, which would only experience temperatures up to a maximum of 90°C. The tags would need to be applied to the area of the product that is exposed to the least heat. The AIDC technology utilised must be able to withstand certain levels of oil, grease and dirt along with levels of damage that could occur throughout the manufacturing operations that the product would be exposed to. The application of an embedded glass tag with an adhesive resin for protection has the ability to withstand such conditions. The fact that the tag is embedded within the part would avoid levels of damage through machining and the adhesive resin used with the glass tag would provide a waterproof and protective coating that would not allow grease, dirt or liquids to reach it. [17-18]

5.0 CONCLUSIONS

The process activity maps highlighted the areas in which the implementation of an AIDC system can add value and the aim of eliminating non-value added operations allowed improvement opportunities to become apparent. The process mapping exercise also provided information that aided the calculation of the cost benefit analysis for an AIDC system through the number of hours saved per process due to improvements. However, due to the fact that the SME pursue job shop manufacturing and make each product specifically to a customer order, it is difficult to predict that each job in the future will have the same timescales or follow the same sequence of operations. The layout of the shop floor at the company was modified in an attempt to facilitate the manufacturing and refurbishments processes as best as possible without compromising one for another. The modified shop floor plan was therefore designed to be the best possible compromise for each of the jobs followed in order to improve the visibility, communication and efficiency throughout the process. The costs associated with the movement of machine and disturbance of production will have to be outweighed against the benefits of the improved layout.

The accurate traceability of products throughout the manufacturing process can improve the efficiency of a process, the accuracy of the information available and improve the lead time of the product. The traceability of parts may be improved through the implementation of an RFID system with components that are capable of withstanding the conditions of the part. Passive LF glass type RFID tags were identified as a viable solution as they may be embedded into the metallic parts produced and can withstand all conditions felt through the products lifecycle. The cost benefit analysis for the SME through the implementation of an RFID system and the modification of the shop floor plan was found to provide a saving of £67,205 annually. Significant cost savings are found through the implementation of an RFID system based on the reduction of safety stock, the elimination of manual job tracking and the reduction of the manual input and written data throughout the process. The modification of the shop layout better facilitated the use of an RFID system as well as improved the efficiency of the process by providing increased visibility and a large reduction in transportation times.

ACKNOWLEDGEMENTS

With thanks to all employees at the SME used in this case study for their input and guidance throughout the course of this project.

ABSTRACT

Collaborative robots (Cobots) have been proposed to guide and assist human operators to move heavy objects in a given trajectory. Most of the existing cobots use steering wheels; typical drawbacks of using steering wheels include (i) the difficulty to follow a trajectory with a curvature larger than that of the base platform, (ii) the difficulty to mount encoders on steering wheels due to self-spinning of the wheels, and (iii) the difficulty to quarantine dynamic control performance since it is purely kinematic control. In this paper, a new cobot with the omni-wheels has been proposed, and its design model has been developed, and a simulation has been conducted to validate this control performance.

1. INTRODUCTION

The collaborative robot (Cobot) is invented by Peshkin and Colgate [1] at Northwestern University. A cobot is a robot designed to assist human beings as a guide or assistor in a constrained motion. In contrast to traditional mobile robots, the cobots provide the guidance rather than moving power. Therefore, they are passive in the sense that the power for fulfilling a moving task is provided by operators. However, the wheels of a cobot are motorized to confine their moving directions when an external force is applied to drive them from planned trajectories. Unlike the robots that perform sophisticated tasks in the restricted areas isolated from operators, the cobots have been designed to work with human operators in a shared workspace [2]; moreover, cobots allow human operators use their muscle power more safely and effectively [3,4].

Most of the cobots are developed for two primary purposes: (i) to assist operators in moving heavy objects under some physical constraints, and (ii) to assist patients or disabilities in navigation or rehabilitation. For purpose (i), Peshkin et al. [5] have proposed a variety of cobots for materials handling. Some cobots for assembly become commercially available from Stanley [6]. Hodgson and Emrich [7] and Townsend et al. [8] have developed and patented a prototype cobot for the surgeons to move C-arm x-ray machines, where the surgeon prefers not to hand over control of a procedure to an autonomous robot. For purpose (ii), Ulrich and Borestein [9] have developed a guide-cane to navigate visually impaired patients. Nejatbakhsh et al. [10] have developed a passive walker for rehabilitation.

Existing cobots mostly use the steered wheels, and their structures are similar to mobile robots with the steered wheels. However, the rolls of the wheels are free in a cobot rather than being controlled in a mobile robot. Therefore, the control mechanisms are significantly different from that of a mobile robot. A few of researchers have studied the controls of the cobots. Peshkin and his collaborators have established the most extensive control models for tricycle cobots. In their works, trajectories are planned in terms of the parameterized arc length, and the rolling speeds of steered wheels have to be detected to decide control parameters [1,3,11-14]. Most of the cobots have three or more wheels; but one or two wheels can also be applied. For example, Ulrich and Borestein [9] have proposed a cobot with two wheels to assist walking for visually impaired patients. It is our observation that a cobot with the steered wheels has the following drawbacks: (i) the difficulty to follow a trajectory with a curvature larger than that of the base platform, (ii) the difficulty to mount encoders on steering wheels because of its self-spinning, and (iii) the difficulty to quarantine the dynamic control performance since it is purely kinematic control.

To overcome the aforementioned drawbacks, we propose to substitute the steered wheels with omni-wheels. Consequentially, a significant difference is that the omni-wheels will be actually controlled by braking torque instead of steering, and dynamic behaviours and corresponding models have to be developed to implement its control. No research has been found on the development of a cobot with the omni-wheels. In fact, very limited research has been conducted to develop the mobile robots using omni-wheels. Nejatbakhsh et al. [10] is the only research group who has been working on the design of the passive walker with four omni-wheels; however, their primary works have been focused on the system identification and the modification of the dynamic characteristics based on a patient’s walking ability. In this paper, a cobot with three omni-wheels is proposed, the kinematic and control dynamic models are established, and the feasibility of its control is evaluated via simulation.

2. CONCEPTUAL SYSTEM DESIGN

The conceptual design of the cobot is shown in Figure 1, the cobot platform is supported by three symmetrically-distributed omni-wheels. Each omni-wheel has a motor allowing the torque applied along its primary rotate axis. At the centre of the cobot platform, the reflectors of a motion tracker are mounted to detect the position and orientation of the cobot platform. An operator will apply the moving force and torque through the operator’s handler, and a 6 DOF (degree of freedom) sensor is used to detect the force and torque of the operator.

![Figure 1: Conceptual design of a cobot with three omni-wheels](image1)

![Figure 2: Cobot parametric model](image2)

The parametric model of the cobot is shown in Figure 2. The motion of the cobot can be described with respect to a world coordinate system \( \{O_w-X_wY_w\} \), and the orientation of the cobot platform is described by three parameters \( \{x_c, y_c, \theta_c\} \) at the origin \( O_c \). In the same way, the centre position of an omni-wheel is described by \( \{x_i, y_i, \theta_i\} \). A local coordinate system \( \{O_c-X_cY_c\} \) is defined on the mobile platform. The locations of the omni-wheels are defined by the parameters \( L_i \) and \( \alpha_i \). \( m_p \) and \( m_i \) are the masses of the mobile platform and an individual omni-wheel, respectively, and \( I_p \) and \( I_i \) are their inertias.

3. KINEMATIC MODEL

The kinematic model describes the relationship between the motions of the omni-wheels and that of the cobot platform. Forward kinematics is concerned in this section; forward kinematics maps a prescribed motion trajectory of the cobot platform into the motions of the omni-wheels.

3.1. THE MOTION OF THE PLATFORM

As shown in Figure 2, the motion of the platform is denoted as \((r_c, \theta_c)\), where \( r_c \) is the origin \( O_c \) of the cobot, and \( \theta_c \) is the z-axis rotation of the cobot platform under the world coordinate system \( \{O_w-X_wY_w\} \). A motion along the prescribed trajectory is described as,

\[
x_c = x_c(t), \quad y_c = y_c(t), \quad \theta_c = \theta_c(t) \quad \text{or} \quad x_c = x_c(s), \quad y_c = y_c(s), \quad \theta_c = \theta_c(s)
\]

where \( t \) is the time variable and \( s \) is the scalar variable representing the arc length along the prescribed trajectory. \( r_c = [x_c, y_c]^T \) is the position of the reference origin of the cobot platform, and \( \theta_c \) is the orientation of the cobot platform.

The velocities and accelerations of the cobot platform with respect to the time \( t \) are as follows,
Design of a Cobot with Three Omni-Wheels

\[ \dot{x}_c = \frac{dx}{ds}, \quad \dot{y}_c = \frac{dy}{ds}, \quad \dot{\theta}_c = \frac{d\theta}{ds} \]

(2)

\[ \ddot{x}_c = \dot{k}_{c_1} + \dot{k}_{c_2} \dot{x}, \quad \ddot{y}_c = \dot{k}_{c_1} + \dot{k}_{c_2} \dot{y}, \quad \ddot{\theta}_c = \dot{k}_{c_1} + \dot{k}_{c_2} \dot{\theta} \]

(3)

where \( k_{c_1} = \frac{d^2x}{ds^2} x^2, k_{c_2} = \frac{d^2x}{ds^2} \), \( k_{c_1} = \frac{d^2y}{ds^2} y^2, k_{c_2} = \frac{d^2y}{ds^2} \), and \( \dot{x}_c, \dot{y}_c, \dot{\theta}_c \) are calculated from eq.(8). Similarly, the acceleration of \( x, y, \theta \) and \( x, y, \theta \) are obtained.

Note that \( \dot{x}_c, \dot{y}_c, \dot{\theta}_c \) depend only on the prescribed trajectory and they can be obtained directly from eq. (1) if the trajectory is known.

\[ \dot{x}_c, \dot{y}_c, \dot{\theta}_c \] will affect the linear velocity \( \dot{x} \) and acceleration \( \dot{y} \) of the motion along the trajectory.

3.2. Derivation of the Motion with Respect to an Arbitrary Parameter

It is common that an explicit description of a trajectory requires a curve parameter other than time or arc length. Therefore, the conversion between different descriptions has to be determined. Assume an arbitrary curve parameter \( q \) has to be used to describe a trajectory explicitly, i.e.

\[ x_s = x_s(q), \quad y_s = y_s(q), \quad \theta_s = \theta_s(q) \]

(4)

Deviating with respect to time \( t \) gets,

\[ \dot{x}_s = \frac{dx_s}{dq} \frac{dq}{dt}, \quad \dot{y}_s = \frac{dy_s}{dq} \frac{dq}{dt}, \quad \dot{\theta}_s = \frac{d\theta_s}{dq} \frac{dq}{dt} \]

(5)

\[ \ddot{x}_s = \frac{d^2x_s}{dq^2} \left( \frac{dq}{dt} \right)^2 + \frac{d^2x_s}{dq^2} \frac{dq}{dt}, \quad \ddot{y}_s = \frac{d^2y_s}{dq^2} \left( \frac{dq}{dt} \right)^2 + \frac{d^2y_s}{dq^2} \frac{dq}{dt}, \quad \ddot{\theta}_s = \frac{d^2\theta_s}{dq^2} \left( \frac{dq}{dt} \right)^2 + \frac{d^2\theta_s}{dq^2} \frac{dq}{dt} \]

However, one has,

\[ \frac{ds}{dt} = \sqrt{\left( \frac{dx_s}{dt} \right)^2 + \left( \frac{dy_s}{dt} \right)^2} = \frac{d^2s}{d\theta_s^2} = \frac{\dot{x}_s + \dot{y}_s}{\sqrt{\dot{x}_s^2 + \dot{y}_s^2}} \]

(6)

Substituting eq. (5) into eq. (6) gives \( \frac{d\theta_s}{dt} = \frac{d^2q}{dt^2} \).

3.3. The Motions of the Omni-Wheel Centres

The position \( r_i \) of the centre of an omni-wheel can be determined from the known posture of \( O_i \) as,

\[ r_i = \begin{bmatrix} x_i \\ y_i \end{bmatrix} = \begin{bmatrix} x_i + L_i \cos(\theta_i + \alpha_i) \\ y_i + L_i \sin(\theta_i + \alpha_i) \end{bmatrix} \quad (i = 1, 2, 3) \]

(7)

Taking the derivation of eq. (7) with the time \( t \) gives the velocity of \( r_i \) as

\[ \frac{dr_i}{dt} = \begin{bmatrix} 1 & 0 & -L_i \sin(\theta_i + \alpha_i) \\ 0 & 1 & L_i \cos(\theta_i + \alpha_i) \end{bmatrix} \begin{bmatrix} \dot{x}_i \\ \dot{y}_i \end{bmatrix} \]

(8)

where \( \dot{r}_i = (\dot{x}_i, \dot{y}_i) \) and \( \dot{\theta}_i \) are calculated from eq.(8). Similarly, the acceleration of \( r_i \) is obtained as

\[ \frac{d^2r_i}{dt^2} = \begin{bmatrix} \ddot{x}_i \\ \ddot{y}_i \end{bmatrix} = \begin{bmatrix} k_{x_i} + k_{y_i} \ddot{x} \\ k_{x_i} + k_{y_i} \ddot{y} \end{bmatrix} \]

(9)

where \( k_{x_i} = \left( \frac{d^2x_i}{ds^2} - L_i \frac{d\theta_i}{ds^2} \cos(\theta_i + \alpha_i) \right) \ddot{x} - L_i \frac{d\theta_i}{ds^2} \sin(\theta_i + \alpha_i), \)

\( k_{y_i} = \left( \frac{d^2y_i}{ds^2} + L_i \frac{d\theta_i}{ds^2} \sin(\theta_i + \alpha_i) \right) \ddot{y} - L_i \frac{d\theta_i}{ds^2} \cos(\theta_i + \alpha_i), \)

\( k_{x_i} = \frac{d^2x_i}{ds^2} - L_i \frac{d\theta_i}{ds^2} \cos(\theta_i + \alpha_i), \)

\( k_{y_i} = \frac{d^2y_i}{ds^2} + L_i \frac{d\theta_i}{ds^2} \sin(\theta_i + \alpha_i) \)

Eqs. (7-9) describe the motion of an omni-wheel with respect to the world coordinate system \( \{O_w-X_wY_w\} \). However, it is convenient to take it into consideration in a local coordinate system of the omni-wheel. The conversion between two motion descriptions is as follows

\[
\begin{bmatrix}
\dot{x}_i \\
\dot{y}_i
\end{bmatrix} = \begin{bmatrix}
ca_i&sa_i \\
-sa_i&ca_i
\end{bmatrix}
\begin{bmatrix}
x_i \\
y_i
\end{bmatrix},
\begin{bmatrix}
\dot{x}_i \\
\dot{y}_i
\end{bmatrix} = \begin{bmatrix}
ca_i&sa_i \\
-sa_i&ca_i
\end{bmatrix}
\begin{bmatrix}
x_i \\
y_i
\end{bmatrix},
\begin{bmatrix}
\ddot{x}_i \\
\ddot{y}_i
\end{bmatrix} = \begin{bmatrix}
ca_i&sa_i \\
-sa_i&ca_i
\end{bmatrix}
\begin{bmatrix}
\ddot{x}_i \\
\ddot{y}_i
\end{bmatrix} = \begin{bmatrix}
k_{x,i1} + k_{x,i2} \ddot{x}_i \\
k_{y,i1} + k_{y,i2} \ddot{y}_i
\end{bmatrix}
\]

(10)

where \( k_{x,i1} = k_{x,i1}ca_i + k_{y,i1}sa_i, \ k_{x,i2} = k_{x,i2}ca_i + k_{y,i2}sa_i, \ k_{y,i1} = -k_{x,i1}sa_i + k_{y,i1}ca_i, \ k_{y,i2} = -k_{x,i2}sa_i + k_{y,i2}ca_i \).

Figure 3: The force analysis of an omni-wheel
Figure 4: The force analysis of the cobot platform

4. DYNAMIC CONTROL MODEL

The torques on the primary rotation axes of the omni-wheels is controlled to confine the cobot platform in the prescribed trajectory. The actual acceleration along the trajectory depends on the external forces applied by an operator and applied torques on the omni-wheels.

4.1. FORCE ANALYSIS OF AN OMNI-WHEEL

The force balance in an omni-wheel is illustrated in Figure 3. The omni-wheel is connected to the cobot platform by \( X' \)-axis of its primary rotation. The reacting force and torque from the cobot platform to the omni-wheel are \( F(F_x,F_y,F_z) \) and \( \tau \). Besides, the omni-wheel has an external normal reacting and friction force \( N_i \) and \( (f_x,f_y) \), respectively, from the ground.

Taking into consideration of the force balance of the omni-wheel gives,

\[
\begin{bmatrix}
F_x \\
F_y \\
F_z
\end{bmatrix} + \begin{bmatrix}
f_x \\
f_y \\
N_i - mg
\end{bmatrix} = \begin{bmatrix}
m_r \ddot{x}_i \\
m_r \ddot{y}_i \\
0
\end{bmatrix}
\]

(11)

where \( F\) \( (F_x,F_y,F_z) \) is the reacting force from the platform to the omni-wheel, \( f_x,f_y \) is the friction force from the ground, \( N_i \) is the normal reacting force from the ground, \( (\ddot{x}_i,\ddot{y}_i) \) is the translational acceleration of the omni-wheel defined in eq. (10), and \( m_r \) is the mass of the omni-wheel.

Taking into consideration of the torque balance gives,

\[
\begin{bmatrix}
\tau \ \\
0
\end{bmatrix} + \begin{bmatrix}
f_x R_x \\
f_y R_y
\end{bmatrix} = \begin{bmatrix}
I_{x} \ddot{\theta}_x \\
I_{y} \ddot{\theta}_y
\end{bmatrix}
\]

(12)

where \( \tau \) is the torque applied to \( X' \)-axis of the omni-wheel, \( I_x \) and \( I_y \) are initial moments of the omni-wheel with respect to \( X' \) and \( Y' \) axes, respectively.
\[ \ddot{\theta}_y = \ddot{\gamma}_y / R_y \quad \text{and} \quad \ddot{\theta}_x = \ddot{\gamma}_x / R_x \] are the angular accelerations of the omni-wheel with respect to the \( X' \) and \( Y' \) axes, respectively. \( R_y \) and \( R_x \) are the radius of the omni-wheel and its rolls.

From eqs. (11-12), \( f_{x_i}, F_{\gamma_i} \) can directly be calculated as,
\[ f_{x_i} = I_y \ddot{x}_y / R_x^2 \]
\[ F_{\gamma_i} = \left( m_x - I_y / R_y^2 \right) \ddot{\gamma}_x \] (13)

Substituting eq. (10) into eq. (13) gives,
\[ f_{x_i} = k_{f_{x_{i1}}} + k_{f_{x_{i2}}} \ddot{s}_{x_i} \]
\[ F_{\gamma_i} = k_{F_{\gamma_{i1}}} + k_{F_{\gamma_{i2}}} \ddot{s}_{\gamma_i} \] (14)

where \( k_{f_{x_{i1}}} = I_y \ddot{x}_y / R_x^2 \), \( k_{f_{x_{i2}}} = I_y \ddot{x}_y / R_x^2 \), \( k_{f_{\gamma_{i1}}} = (m_x - I_y / R_y^2) \ddot{\gamma}_x \), \( k_{f_{\gamma_{i2}}} = (m_x - I_y / R_y^2) \ddot{\gamma}_x \).

\( f_{x_i}, F_{\gamma_i} \) can be expressed in terms of the unknown variable \( \tau_i \) as,
\[ F_{\gamma_i} = m_y \ddot{\gamma}_y + \left( \tau_i - I_y \ddot{\gamma}_y / R_y \right) / R_y \]
\[ f_{x_i} = \left( -\tau_i + I_y \ddot{\gamma}_y / R_y \right) / R_y \] (15)

Substituting eq. (10) into eq. (15) gives,
\[ f_{x_i} = k_{f_{x_{i1}}} + k_{f_{x_{i2}}} \ddot{s}_{x_i} + k_{f_{\gamma_{i1}}} \ddot{s}_{\gamma_i} + k_{F_{\gamma_{i1}}} \ddot{s}_{\gamma_i} \]
\[ F_{\gamma_i} = k_{F_{\gamma_{i1}}} + k_{F_{\gamma_{i2}}} \ddot{s}_{\gamma_i} + k_{F_{\gamma_{i1}}} \ddot{s}_{\gamma_i} + k_{F_{\gamma_{i2}}} \ddot{s}_{\gamma_i} \] (16)

where \( k_{f_{x_{i1}}} = I_y \ddot{x}_y / R_x^2 \), \( k_{f_{x_{i2}}} = I_y \ddot{x}_y / R_x^2 \), \( k_{f_{\gamma_{i1}}} = (m_x - I_y / R_y^2) \ddot{\gamma}_x \), \( k_{f_{\gamma_{i2}}} = (m_x - I_y / R_y^2) \ddot{\gamma}_x \), \( k_{F_{\gamma_{i1}}} = 1 / R_y \), \( k_{F_{\gamma_{i2}}} = 1 / R_y \).

Note that the following constraint applies to prevent the slip:
\[ \sqrt{f_{x_i}^2 + F_{\gamma_i}^2} \leq \mu_N \] (17)

where the normal reacting forces from the ground to the omni-wheels can be determined from the following equations,
\[ \sum_{i=1}^{3} N_{x_i} + F_{ec} x = 0 \]
\[ \sum_{i=1}^{3} N_{y_i} = (m_x + 3m_e) g + F_{ec} \]

\[ \text{4.2. FORCE ANALYSIS OF THE PLATFORM} \]

As shown in Figure 4, the cobot has an external force \( F_e \) and torque \( \tau_e \) applied by a human operator. The force and torque are uncontrollable. A force sensor has to be applied to measure their values and directions in real-time. When the cobot platform is isolated from the omni-wheels, the reacting forces \( -F_{x_i}, -F_{y_i}, -F_{\gamma_i} \) and torque \( -\tau_i \) from the omni-wheels are considered to be external.

Taking into consideration of the force balance on the plane of \( X_wY_w \) with respect to the local coordinate system on the platform gives,
\[ F_e - \sum_{i=1}^{3} \begin{bmatrix} c\alpha_i & -s\alpha_i \\ s\alpha_i & c\alpha_i \end{bmatrix} F_{x_i} = m_x \begin{bmatrix} c\theta_e & -s\theta_e \\ s\theta_e & c\theta_e \end{bmatrix} \tau_e \] (18)

In eqs. (14) and (16), the forces on the omni-wheels are obtained in the local coordinate systems of the omni-wheels. They have to be transformed into the same coordinate system, i.e., the local coordinate system on the cobot platform.
Substituting eqs. (6), (14) and (16) into eq. (18) gives,

\[
F_{x,x} = -\sum_{i=1}^{3} \left[ ca_i \left( k_{x,i} + k_{x,i} \dot{s} \right) - sa_i \left( k_{y,i} + k_{y,i} \dot{s} + k_{z,i} \tau \right) \right] = m_p \left( k_{x,1} \theta_x - k_{y,1} \dot{\theta}_y + k_{z,1} \dot{\theta}_z \right) + \left( k_{x,2} \theta_x - k_{y,2} \dot{\theta}_y + k_{z,2} \dot{\theta}_z \right) \dot{s}
\]

\[
F_{y,y} = -\sum_{i=1}^{3} sa_i \left( k_{x,i} + k_{x,i} \dot{s} \right) + ca_i \left( k_{y,i} + k_{y,i} \dot{s} + k_{z,i} \tau \right) = m_p \left( k_{x,1} \theta_x + k_{y,1} \dot{\theta}_y + k_{z,1} \dot{\theta}_z \right) + \left( k_{x,2} \theta_x + k_{y,2} \dot{\theta}_y + k_{z,2} \dot{\theta}_z \right) \dot{s}
\]

\[
(19)
\]

The above equation can be changed into the following form,

\[
U_{11} \tau_1 + U_{12} \tau_2 + U_{13} \tau_3 + U_{14} \dot{s} = U_{15}
\]

\[
U_{21} \tau_1 + U_{22} \tau_2 + U_{23} \tau_3 + U_{24} \dot{s} = U_{25}
\]

where \(U_{ij}\) is the co-efficient determined from eq. (19).

Taking into consideration of the torque balance with respect to \(Z_w\) gives,

\[
\tau_e + F_e \times r_e - \sum_{i=1}^{3} \left[ ca_i \left( k_{x,i} + k_{x,i} \dot{s} \right) - sa_i \left( k_{y,i} + k_{y,i} \dot{s} + k_{z,i} \tau \right) \right] F_{i,x} \times r_e = I_p \dot{\theta}_i
\]

\[
(21)
\]

where \(I_p\) is the inertial moment of the platform with respect to \(\{O_c-X_c-Y_c-Z_c\}\), \(r_e\) is vector from the reference origin to the location of the force is applied and detected, and \(\tau_e\) is external torque with respect to \(Z_w\) applied by a human operator.

Substituting the eqs. (14) and (16) into the eq. (21) gives,

\[
U_{31} \tau_1 + U_{32} \tau_2 + U_{33} \tau_3 + U_{34} \dot{s} = U_{35}
\]

\[
(22)
\]

where \(U_{3i} = k_{j_i} \dot{L_i}, U_{34} = -I_p k_{g,2} - \sum_{i=1}^{3} k_{j_i} \dot{L_i}, U_{35} = -I_p k_{g,1} - F_e \times r_e - \sum_{i=1}^{3} k_{j_i} \dot{L_i}
\]

Combining eqs. (20) and (22) makes a set of three linear equations. When \(\tau_i\) \((i=1,2,3)\) are dealt with design variables, they can be solved and represented by \(\ddot{s}\) as,

\[
\tau_i = k_{x,i} \ddot{s} + k_{y,i} \ddot{s} \quad i = 1,2,3
\]

\[
(23)
\]

where \(k_{x,i}, k_{y,i}\) are the coefficients determined \(U_{ij}\) in eqs. (20) and (22).

4.3. Constraints to maintain the ground contact

When the torques applied on the axes of the omni-wheels, they will change the distributions of the normal reacting forces from the ground. These normal reacting forces depend on the external force by the human operators and the torques applied on the omni-wheels. The model of determining these forces has been developed but not included in this paper. These forces have to be positive so that appropriate contacts can be maintained between the cobot and the ground.

5. Case study

As shown in Figure 9, the output of the control is the motion acceleration required to follow the planned trajectory, and the inputs of the control include (i) the prescribed trajectory that can be revised based on the real-time feedback, (ii) the detected position and orientation of the cobot platform, (iii) the detected translational and rotational velocities of the cobot platform, and (iv) the detected force and torque applied by a human operator.

In the conceptual design, the following input parameters are assumed,

(i) the omni-wheels are distributed symmetrically as \(L_i = 0.3\ m, \alpha_1 = -\pi/6, \alpha_2 = -\pi/2, \alpha_3 = 7\pi/6;\)
(ii) the platform has a mass $m_p=600$ kg, and $I_{pc} = m_p L^2/4$;
(iii) the location of the force sensor is $r_e = (0, L/2, 0)$;
(iv) the parameters of an omni-wheel are $R_o=0.02$ m, $m_o=0.5$ kg, $I_{ao}=m_o R_o^2/4$;
(v) the parameters of a roll on an omni-wheel are $R_e=0.005$ m, $m_e=0.05$ kg, $I_{ae}=m_e R_e^2/4$;
(vi) the required trajectory is defined in term of the trajectory parameter $q$ as
   \[ x = 0.125q + 0.8 \cos(q) - 1.0, \quad y = 0.8 \sin(q), \quad \theta = 0.1q; \]
(vii) the external forces are assumed as,
   \[ \angle(F, Y) = 0.25 \pi (1 - 2 \times \text{rand}()), \]
   \[ F_x = [100 + 50(1 - 2 \times \text{rand}())] \cos(\angle(F, Y)), \]
   \[ F_y = [100 + 50(1 - 2 \times \text{rand}())] \sin(\angle(F, Y)), \]
   \[ F_c = [-100 - 50(1 - 2 \times \text{rand}())], \]
   \[ \tau_c = 0.05(1 - 2 \times \text{rand}()). \]

where $\text{rand}()$ represents a randy number between (0.0, 1.0) and $\angle(F, Y)$ is the angle between the project of $F_e$ on the plane $X_Y$ and $Y$. The gravity acceleration and the friction coefficient are assumed to be 9.81 $kg/m^2$ and 0.1, respectively. The simulation results from the developed control model are demonstrated in Figures 5-8.
The graphic simulation model has been developed for the validation of the control model. The results have shown that it is feasible to control a cobot with the omni-wheels to follow a specified trajectory by applying controlled torques on the primary axes of the omni-wheels. The applied torques will be transformed into the reacting friction forces from the ground to the omni-wheels, and the reacting friction forces will be combined with the external forces and torque applied by an operator to generate a motion acceleration along the given trajectory. Figure 8 shows that the applied torques are not always to decelerate the wheel rotation; either positive or negative torque can be required. In particular, when the trajectory includes a rotation of the cobot platform, the torques applied on the omni-wheels at two sides are opposite. Graphic simulation has been developed to validate the controlled motion of a cobot platform, and Figure 10 depicts a screen shot of the cobot motion in simulation.

6. CONCLUSIONS

In this paper, a new cobot with the omni-wheels is proposed, its kinematic and dynamic models are developed, and the simulation is conducted to illustrate its feasibility. The cobot can be used as a vehicle to move a bulky device along a specified trajectory. A unique feature of the new cobot is its redundant control; the number of the control variables is more than the DOF of the cobot motion. Note that the existing cobots are purely passive and operated manually, and some fully automated active robots have their disadvantages in terms of the safety and cost issues. The most significant advantage of the new hybrid cobot is that the degrees of manual or machine operations of the system can be adjusted in the control model. Therefore, the modes of the manual operation, the full automation, and in-between can be selected and switched based on operation requirements.

**ABSTRACT**

Diffusion reflection measurements from different plane surfaces using a laser diode light are reported. A double-fiber arrangement is used in which one fiber transmits the laser light to the sample surface and the second one transmits the reflected light to the photodetector for the signal measurement. The novelty of reported design is that it compactness of the fiber probe, its simplicity, and it is possible to use the source and the detector at the same side. The intensity measurements for the transparent dielectric, matte plastic surfaces and colored papers are presented in this report. For the thick color plastics, the yellow color has the highest reflectance and the black one shows the lowest. For the thin colored papers the yellow paint shows a maximum diffuse reflectance, whereas, the gray has the lowest diffuse reflectance. Our results in general agree well with the theoretical predictions and also with the other experimental results of diffuse reflection at a near source wavelength. Reflection information reported by this method can be useful in analysis of laser material processing and imaging processes considering the role of reflected light. It can be also useful in design of displacement sensor for object tracking and recognition, vision systems in automotive industry or any automated industry.

1. INTRODUCTION

When a ray of light strikes the surface of an object, it may be absorbed, transmitted, or reflected. Considerable attention has been paid to reflectance study of various surfaces. Some studies have concentrated on the experimental determination of surface reflectance, and at the same time, many theories have been developed for surface reflection modeling [1]. Two limiting cases have been considered at the early stages: the light reflected in a particular direction (perfect specular), or the light reflected in all directions of a hemisphere above the surface uniformly (Lambertian). These two ideal cases for a surface are never attained in practice, and it is advisable to consider both effects to describe the reflection properties of a surface. The distribution of the reflected light in each case described depends on the light direction, wavelength, polarization, and details of the microstructure of the surface layer. For the symmetric surfaces, the reflection is not altered by rotating a surface path about its normal, while in the case of asymmetric surfaces, there is a preferred direction (diffraction in grating). Many surface layers are symmetric and this results certain degree of simplification of the analysis.

In most experiments light from lamps or laser sources have been used to measure surface properties. The use of laser light in the study of metallic surfaces has been reported by Tanner [2]. Optical methods including specular and diffuse reflection measurements have been given. Considering the importance of both specular and diffuse reflectance, in this article we report the relative reflection measurements from surfaces made from different materials, which can provide new and useful information in this respect.

2. THEORY OF REFLECTION

A reflection theory, which considers the surface radiance as a function of both incident and reflected beam, is given by Berthold et al. [3]. In that model, a function denoted by $f_r$ indicates the information about how bright a surface will appear, when viewed from a given direction. The bidirectional reflection distribution function (BRDF), defined in that report, shows the ratio of reflected radiance in a direction toward a portion of the surface. A number of theoretical approaches have been developed to explain the scattering characteristics of rough surfaces [4]. Sinusoidal, sawtooth, rectangular, and random profiles have been used in such studies. Another model considers the particle theory in which a powder sample is treated as a collection of uniformly sized rough surfaced spherical particles. The effect of roughness on the specular reflection has led to the development of many models. A surface is modeled as a collection of specular vertices in which the surface normals are assumed to be normally distributed. This is known as the Torrance-Sparrow model [5] that is widely used in the computational vision system and graphics.

It has been shown that geometrical optics is applicable when the surface irregularities are much larger than the wavelength of the incident light. As reported in such cases the Torrance-Sparrow model approximates the physical optics model developed by Beckman and Spizzichino [7]. A number of alternative physical-optics approaches to the problem have been described in the literature [8]. All the above models ignore the effect of roughness on the diffuse reflection, which is the major drawback of both theories. For surface layers it is possible that light reflected from two different physical paths. Some light is reflected at the interface, and the second occurs for the light that crosses the interface. Tominaga and Wandell [9] reported a standard surface reflection model and illuminant estimation for inhomogeneous materials by using two independent mechanisms. The result of that study can be used to describe the light reflected from inhomogeneous materials, measured in different viewing geometries, to estimate the relative spectral power distribution of the ambient light.

Scattering from metallic and dielectric rough surfaces is discussed by Sallier and Maystre [10], by using the integral theory of metallic and dielectric gratings. Wolff [11, 12] has reported diffuse-reflectance model for smooth dielectric surfaces. Light reflectance from randomly oriented convex particles with rough surfaces has been reported. They considered large particles in comparison with the wavelength and calculated the differential scattering cross section. In another study absolute diffuse reflection from relative reflectance measurements has been reported by Lindberg [13]. In this article, we present some of the results given by Ginnken et al. [14], which is useful to our discussion. The total diffuse radiance corrected for masking and shadowing effects is given by integration in Ref. [15]. The total radiance according to Ref. [14] can be the sum of the specular and diffuse reflections

$$L_r = C[gL_{rs} + (1 - g)L_{rd}] ,$$

where $L_{rs}$ shows the specular and $L_{rd}$ the diffusion reflection. In Eq. (1) parameter $g$ indicates the balance between the diffuse and specular reflections, changes between 0 and 1. The parameter $C$ accounts for the intensity normalization factor.

The reflection of transmitted light from a surface based on the geometrical optic can be obtained easily. In this case, the image of the transmitted light on the entrance plane (image plane) of the receiving fiber is computed. Three distinct cases can be considered for such analysis. Let us consider the beam cross second on the target plane to be circular in the $xy$-plane, with the $z$-axis showing the direction of the propagation of the beam. Consider the horizontal and $y$-axis as vertical axis in the object and image planes. If $r_1$ and $r_2$ represent the transmission (T-fiber) and receiving fibers (R-fiber), respectively, then the overlap of two circles determines the amount of light received by receiving fiber. First case when there is no crossing of two circles, no specular light is received by the R-fiber. When diameter $AB$ is tangent or inside the larger circle, the light is received. The amount received light depends on the amount of the crossing area between these two circles. Using geometrical relations, one can compute $\Delta S$ for two described cases. The light intensity on the surface is given by

$$I = \frac{P_o}{\Delta S}.$$
Where \( P_0 \) is the incident power transmitted by the T-fiber. The power, \( P \), collected by the receiver fiber can be written as

\[
P = \rho I \Delta S,
\]

(3)

where \( \rho \) shows the overall reflection coefficient for the reflecting surface. The maximum value of the \( \Delta S \) can be equal to the area of R-fiber cross section. For a similar double-fiber such as the one used here the core radius for two fibers are equal. The intensity of light entered in T-fiber varies by the axial distance between the fibers and the target plane. Theoretical and experimental result indicate that by increasing distance from zero, the collected power is increased, at a particular distance is at maximum, and further increase causes a decrease in the collected power. For our case the distance at which the signal is maximum is used for all the reflection measurements.

3. EXPERIMENTAL ARRANGEMENT

The instrumental arrangement for this study is presented in Fig. 1. The light source is a 5-mW laser diode operating at 650 nm wavelength. A silicon photodiode (BPX 65 Centronic) is used for light detection and conversion of optical signal to an electric one. The photodiode is reverse biased to \(-18\) V by using a battery pack and operates in the photoconductive mode. The electric output signal of this detector is connected to a digital voltmeter (0.1 mV precision) by a coaxial cable. For optimum detection, a flexible adjusting mechanism is required, so the reflecting surface is mounted on a transnational stage, which provides a fine and smooth movement of the surface in axial direction. This assembly provides a simple and precise way to collect all the reflected light even by using a small area photodetector. To collect data the output signal of the photodetector is connected to a digital multimeter (DMM) as shown in Fig. 1. The output of this DMM (Sanwa, PC-5000) can be interfaced to a PC.

![Figure 1: Experiment set up including a laser diode, a double-fiber, a photodetector, a digital voltmeter and a PC](image)

As can be seen in Fig. 1, a double fiber is used in this experiment in which in one end two fibers are separated and they are close to each other at the other end. The double end is mounted in a proper holder close to the surface under study. The separated fiber ends are connected to the laser diode source and detector accordingly. The double fiber includes similar plastic step-index fibers. The overall diameter of each fiber is about 2 mm, and the core diameter is about 860 \( \mu \)m. The numerical aperture for such fiber is about 0.41. The double fiber is cut from the purchased spool and the fiber ends are simply cleaved and polished. However, a better treatment of the fiber ends can improve the coupling efficiency of the fiber to source, to surface under study, and finally to photodetector. Since the cross section of the fiber is large enough, therefore, the laser light is directly coupled to the fiber. Such direct coupling is very easy and does not require any lens and thus the coupling efficiency is higher for such a big-core fiber.
The laser power is about 3 mW and the transmitted power to the surface is about 0.3 mW as measured by a laser power meter. The double side of the fibers is fixed firmly in a proper holder in a distance of about 10 mm from the surface under study.

Two groups of samples are used for this experiment and each sample could be easily fixed at its place for measurements. In sample placement care was taken to place the plane sample test in perpendicular position to the optical axis (fiber axis). For the better adjustment, a plane mirror is used in place of the sample and optimum situation is obtained. Our samples include: the plastic materials, and thin and thick color papers with the similar thickness in each category group.

4. EXPERIMENTAL RESULTS

Using the experimental arrangement shown in Fig. 1 the diffusion reflection signal is measured and results are described in this section. Each measurement is repeated at least 5 times and average value was recorded for the related sample is quoted here. Diffuse reflectance measurements from different surfaces are reported in Ref. [15]. In that experiments a He-Ne laser has been used for measurements. As concluded in [15], dependence of the reflected light upon the light characteristics and details of the surface structure leads to a complicated problem of interaction of light from surfaces. The mixed reflectance considering both the diffuse and specular reflectance from a surface must be considered in any surface modeling. Experimentally, measurements of both specular and diffuse reflections are required in order to test a model or to describe a surface. In metallic surfaces usually the specular reflection is the predominant, so one expects that the diffuse reflectance to be very smaller than specular reflectance.

In the first study the light reflected off the different plastic surfaces is measured and the output signals are shown in Fig. 2 and 3. Both thick and thin color plastics are studied in this investigation. Fig. 2 shows the reflection signal measurements for the similar matte plastics with different colors.

![Figure 2: Reflection measurement for the matte plastics with different colors](image)

Here as can be seen in Fig. 2, the white color matte plastic has the highest reflectance (292 mV); while the blue color shows the minimum diffuse reflection (146 mV). In a similar study the relative reflectance for transparent dielectric materials such as plastics, Kapton, and Mylar sheets were examined. Among these materials with different colors the clear blue sheet has the lowest diffuse reflection, while the Mylar sheet shows the highest diffuse reflection.
We have measured the relative diffuse reflectance for some clear dielectric materials. These materials include: a piece of black rubber (2 mm thickness), a piece of printed circuit board dielectric material (1.5 mm thickness), a piece of dark Plexiglas (3 mm thickness), a clear Plexiglas plate (3 mm thick), and white matte plastic (1 mm thickness). Among tested materials, black rubber shows the lowest diffuse reflectance signal, while the white plastic material shows the highest diffuse reflectance signal (figure not shown here).

For the transparent plastic sheet, the reflection results for some different materials are shown in Fig. 3. In this experiment, colorless, red, dark blue, light blue, and green plastic materials are tested. As can be seen in this comparison, the colorless sheet shows the highest diffuse reflection (292 mV), while the green one has the lowest reflection signal of about 132 mV. In any experiment, the reproducibility of the obtained results is a very important factor. To check this point for this experiment as shown in Fig. 2, two series of the experimental results are compared with each other. Looking at the results, it is noted that there is a very good agreement between the result of series 1 and series 2 as plotted in Fig. 2. Such procedure is repeated for all the experimental results reported in this study as can be seen in different figures representing the results. The difference in the obtained results is less than 1% of the full scale value, which is a good reproducibility for such measurements. Another important factor in such measurements is the stability of the experimental results. Operation and time stability of the measuring instrument is checked and shows a very good stability for a time period of about 10 minutes.

In another study, we considered different plastic materials and the results for thick materials are presented in Fig. 4. The reflection signals are measured for such different thick color materials with a thickness of about 0.5 mm. Among different colors as indicated in graph bar of Fig. 4, the yellow color has the highest diffuse reflectance (303 mV); while the black color shows the least diffuse reflection of about 113 mV.
Figure 4: Reflection signal measurements for thick plastics with different colors

Figure 5: Reflection signals for the thin color papers
In the next study we considered paper materials and the results for thick, thin, and glossy papers are presented in this study. Fig. 5 shows the reflection signals measured for thin color papers. The relative diffuse reflectance for the colored thin papers with a thickness of about 0.5 mm is measured. Among different colors the yellow one has the highest diffuse reflectance (300 mV); while the gray color shows the least diffuse reflection of about 208 mV.

A similar study was accomplished for the colored papers and the results are shown in Fig.6. For different colors the yellow one has the highest diffuse reflection (304 mV), while the blue color has the minimum diffuse reflection (115 mV) at this wavelength. For comparison the reflection for the standard A4 paper is also shown in Fig. 5 and Fig. 6.

![Figure 6: Reflection signals measured for thick color papers](image)

![Figure 7: Reflection signal measurements for the glossy papers with different colors](image)
In order to compare the results of this study for the color thin papers (Fig.5), and for thick color papers (Fig.6) the results have been normalized to the output of the A4 white paper as indicated in both figures. The reflectance signals of the similar glossy papers are also investigated in this study (see Fig.7). The result of this study indicates that glossy cream paper has the highest diffuse reflection (327 mV) while the blue color shows the minimum diffuse reflection (134 mV). It must be pointed out that both color and material types control the reflection signals as described in this study.

5. CONCLUSIONS

In many applications such as in vision system, laser scanners, laser imagining, laser Doppler measurements, and laser material processing the reflection of the light from the surface of illumination is of great interest. This article described the diffuse reflection from different plane surfaces. Results of this work together with the information provided for the specular reflectance can be helpful in the field of for example computer graphics and vision systems, which are based on image formation from reflected light from an object surface. Such reflection information can be also useful in design of non-contact displacement sensor for object tracking and recognition in automotive industry or other automated industries. Sensing operation can provide information about the position of the part and vision system, in particular, can provide information about the shape of surface under study. Resulting data can be used to extract information such as physical properties of different materials and layers as well.

ABSTRACT

In this paper, we present an analytical model for autonomous vehicle storage and retrieval system (AVS/RS). The system is modeled as semi-open queuing network (SOQN). An SOQN consists of jobs, pallets and servers. Each job is paired with a pallet and the two visits the set of servers required for processing the job in the specified sequence. In the network of an AVS/RS, storage/retrieval (S/R) transactions are jobs and the autonomous vehicles are pallets. If an S/R transaction requires a vertical movement it uses lift. The lifts and horizontal travel times to/from a storage space are the servers. First, we describe all possible scenarios and their probabilities to derive the general service times. Second, we combine all the service times of the network. Last, we solve the SOQN using an approximate method and obtain the performance measures. The case study is completed for a company that uses AVS/RS in France.

1. INTRODUCTION

Autonomous vehicle storage and retrieval systems (AVS/RS) represent a relatively new technology for automated unit load storage systems. Autonomous vehicles function as storage/retrieval (S/R) devices. Within the storage rack, the key distinction of AVS/R systems relative to traditional crane-based automated storage and retrieval systems (AS/RS) is the movement pattern of the S/R device. The vehicles in an AVS/RS share a fixed number of lifts for vertical movement and follow rectilinear flow patterns for horizontal travel.

It is crucial to design an AVS/RS in such a way that it can efficiently handle the current and future demand requirements while avoiding bottlenecks and having excess capacity. Due to the relative inflexibility of the physical layout and the equipment, it is important to design it right the first time. To be able to evaluate all possible design scenarios, an efficient, valid model that is not time consuming is required. The purpose of this study is to develop an analytical model for AVS/RS.

2. BACKGROUND AND DISCUSSION

An AVS/RS transports a unit load using rail guided automated vehicles (AVs) that follow three-dimensional rectilinear movement patterns. The major system components of the AVS/RS technology are lift mechanisms that are mounted along the periphery of the storage rack to provide vertical movement. The dominant cost component of the AVS/RS technology is the vehicle. Lifts costs are approximately 25% of those for the vehicles.

In most unit-load S/R systems, space-conserving random storage policies are used because of capital cost considerations [1]. Under a random storage policy, the location of a specific load in a storage system is a random variable over time. This policy ensures space occupancy rate maximization by allowing different loads to occupy the same addresses at different times [2].

There are various studies that evaluate the performance of AVS/RSs ([3], [4], [5], [6], [7], [8]). Different from those studies, we model the AVS/RS with a SOQN approach. We use an approximate based solution to solve the SOQN. We use ARENA 12.0 a commercial simulation software, to develop the simulation results.

3. SOQN NETWORK MODELING OF AVS/RS

An SOQN consists of jobs, pallets and servers. Each job is paired with a pallet and the two visits the set of servers required for processing the job in the specified sequence. The AVS/RS queuing system can be modeled as a SOQN. In the network of an AVS/RS, storage/retrieval (S/R) transactions are jobs and the autonomous vehicles are pallets. The lifts and horizontal travel times to/from a storage space are the servers and the transactions are customers. Each transaction needs vehicle before it can enter the network. Thus, the total number of transactions in service or waiting for service in the network cannot be larger than the number of vehicles. Figure 1 shows the SOQN model of the AVS/RS. If a vehicle is available, then an arriving transaction enters the network of servers immediately, along with this vehicle. Otherwise, it waits in the transaction queue until a vehicle becomes available. When a transaction exits the system, the vehicle returns to a ‘vehicle’ pool.

![Figure 1: Semi-open queuing network](image)

SOQN assumptions and formulations are given below:

1. The dwell point of a vehicle is the place where the last storage or retrieval transaction is completed.
2. The dwell point of the lift is where the last vertical movement is completed.
3. Available locations are chosen randomly for storage of unit-loads.
4. The number of aisles, columns (bays) and tiers of an actual installation are used to derive the probabilities.
5. The arrival rates for storage and retrieval transactions are independent Poisson processes and equal.
6. The transactions are served by the vehicles on a first come first served (FCFS) rule. The vehicles requiring lifts for vertical movement are also served by FCFS order.

The notation used in the AVS/RS model is given below:

- $A$: number of aisles on each tier
- $T$: number of tiers
- $W$: the width of one storage bay
- $V$: the number of vehicles
- $Y_x$: the distance from the 1st bay to the cross aisle
- $v_L$: the velocity of the lift
- $\lambda_S$: the arrival rate of storage transactions per hour
- $C$: number of bays (columns) per aisle
- $D$: the distance between two aisles
- $H$: the height of one tier
- $L$: the number of lifts
- $T_T$: load or unload transfer time between the lift and the I/O point.
- $v_v$: the velocity of the vehicle
- $T_{LU}$: the time to load/unload to or from the storage
\( \lambda_R \): the arrival rate of retrieval transactions per hour

Because of the agreement with the company, we do not give the specific values of the parameters defined above, except the below parameters:

\[
\begin{align*}
A &= 42 & L &= 7 & C &= 27 \\
T &= 7 & \lambda_S &= 225 \text{ unit-loads} & \lambda_R &= 225 \text{ unit-loads}
\end{align*}
\]

3.1 SCENARIOS FOR MOVEMENT KINEMATICS

To be able to derive the expected service time of a transaction, all probable scenarios are considered. In this section, we define all probable scenarios of transactions and their probabilities.

3.2 SIX TRAVEL SCENARIOS FOR STORAGE TRANSACTIONS

We define six travel scenarios and their probabilities for the storage transactions. \( Sf \) shows that the requested storage location is on the first tier. \( Sn \) means the requested storage location is not on the first tier. \( Vo \) and \( Vf \) mean that the seized vehicle is at the I/O point, and at the first tier but not at the I/O point, respectively. And, \( Vn \) indicates that the seized vehicle is not on the first tier.

**Scenario 1 (VnSn)** - The seized vehicle is not on the first tier and the requested storage position is not on the first tier: Under this condition, the expected travel distance is calculated by considering five movements: (i) Vehicle travels from its current position to the lift (ii) Lift travel from its current tier to the vehicle’s tier (iii) Vehicle travel in the lift to the I/O tier (iv) Loading and lift travels to the destination tier (v) Vehicle travels to the destination storage and unloads the unit-load.

**Scenario 2 (VnSf)** - The seized vehicle is not on the first tier and the requested storage position is on the first tier. Under this condition, the expected travel distance: (i) The vehicle travels from its current position to the lift (ii) Lift travel from the current tier to the vehicle’s tier (iii) The vehicle travels to the I/O (iv) Unit-load is loaded on the vehicle (v) The vehicle travels to the destination storage unloads the unit-load.

**Scenario 3 (VfSn)** - The seized vehicle is on the first tier and the requested storage position is not on the first tier. Under this condition, the expected travel distance: (i) Vehicle travels from its current position to the lift (ii) Lift travels to the first tier (iii) Unit-load is loaded and, lift and vehicle travel to the destination tier (iv) The vehicle travels to the storage rack and unloads the unit-load.

**Scenario 4 (VoSn)** - The seized vehicle is at the I/O point and the requested storage position is not on the first tier. The expected travel distance: (i) Lift travels from its current tier to the first tier (ii) Unit-load is loaded on the vehicle and, the lift and vehicle travel to the destination tier (iii) The vehicle travels to the storage rack and unloads the unit-load.

**Scenario 5 (VfSf)** - The seized vehicle is on the first tier and the requested storage position is on the first tier. The expected travel distance: (i) The vehicle travels from its current position to the lift (ii) Lift travels from its current tier to the first tier (iii) Unit-load is loaded on the vehicle (iv) The vehicle travels to the destination storage unloads the unit-load.

**Scenario 6 (VoSf)** - The seized vehicle is at the I/O point and the requested storage position is on the first tier. (i) Lift travels from its current tier to the first tier (ii) Unit-load is loaded on the vehicle (iii) The vehicle travels to the destination storage unloads the unit-load.

3.3 STORAGE SCENARIOS’ PROBABILITY CALCULATIONS

The occurrence probabilities for the above six scenarios are calculated in Table 1.
Table 1: Probabilities of six storage scenarios

3.4 SEVEN TRAVEL SCENARIOS FOR RETRIEVAL TRANSACTIONS

The same calculations are also completed for the retrieval transactions. We also describe the first scenario different from the storage transaction scenarios, \( Rf \) and \( Rn \) mean that the retrieval location is (is not) on the first tier.

**Scenario 1 (VnRn):** The seized vehicle’s and requested retrieval positions are not on the same tier and the retrieval location is not on the first tier.

**Scenario 2 (VoRn):** The seized vehicle is at the I/O point and the retrieval location is not on the first tier.

**Scenario 3 (VnRn):** The seized vehicle and the retrieval location are on the same tier other than the first.

**Scenario 4 (VnRf):** The seized vehicle is not on the first tier and the retrieval location is on the first tier.

**Scenario 5 (VfRf):** The seized vehicle and the retrieval location are on the first tier.

**Scenario 6 (VoRf):** The seized vehicle is at the I/O point and the retrieval location is on the first tier.

**Scenario 7 (VfRn):** The seized vehicle is on the first tier and retrieval location is not on the first tier.

3.5 RETRIEVAL SCENARIOS’ PROBABILITY CALCULATIONS

The retrieval transaction scenarios’ probabilities are obtained as Table 2.

Table 2: Probabilities of seven retrieval scenarios

<tr>
<td>Pr (R₁)  = \frac{T-2}{T} \times \frac{\lambda_S}{\lambda_S + \lambda_R} \times \frac{T-1}{T}</td>
<td>Pr (R₄) = \frac{T-1}{T} \times \frac{\lambda_S}{\lambda_S + \lambda_R} \times \frac{1}{T}</td>
</tr>
<tr>
<td>Pr (R₂)  = \frac{\lambda_R}{\lambda_S + \lambda_R} \times \frac{T-1}{T}</td>
<td>Pr (R₅) = \frac{1}{T} \times \frac{\lambda_S}{\lambda_S + \lambda_R} \times \frac{1}{T}</td>
</tr>
<tr>
<td>Pr (R₃)  = \frac{1}{T} \times \frac{\lambda_S}{\lambda_S + \lambda_R} \times \frac{T-1}{T}</td>
<td>Pr (R₆) = \frac{\lambda_R}{\lambda_S + \lambda_R} \times \frac{1}{T}</td>
</tr>
<tr>
<td>Pr (R₇)  = \frac{1}{T} \times \frac{\lambda_S}{\lambda_S + \lambda_R} \times \frac{T-1}{T}</td>
<td>Pr (R₇) = \frac{\lambda_R}{\lambda_S + \lambda_R} \times \frac{1}{T}</td>
</tr>
</tbody>
</table>

3.6 CUSTOMER COMBINATION

Each scenario of storage and retrieval transaction has different routes and service times. Therefore, each scenario can be seen as a new transaction (customer) type in the queuing system. Thus, we have a multi-product SOQN which has 13 (6+7) types of transactions (customers). When the network servers have general service time distributions, they usually defined by two moments which are the mean and the squared coefficient of variation (scv) of service times. Scv is the ratio of the variance to the mean square.

The multi-class queuing network can be treated as a single-class network using Expressions (1)-(6) (see, [9]). Notations that are used for this technique is given below:

- \( n \) : number of nodes
- \( k \) : number of classes
- \( m_j \) : number of servers at node \( j \)
- \( p_{ij}^r \) : routing probability of class \( r \)
- \( \lambda_0^r \) : external arrival rate of class \( r \)
- \( c_j^2 \) : the scv of the service-time distribution of node \( j \)
\( \lambda_i^r \): arrival rate of class \( r \) to node \( i \)

\( \tau_j^r \): the mean service time of class \( r \) at the \( j \)th node of its route

\( c_{ij}^2 \): the scv of the service-time distribution of class \( r \) at the \( j \)th node of its route

According to that technique first, we obtain the external arrival rates to each node calculated by (1):

\[
\lambda_{0j} = \sum_{r=1}^{k} (b \times \lambda_0^r) \quad \left\{ \begin{array}{l}
 b = 1, \text{ if node } j \text{ is the first node on route class } r \\
 0, \text{ otherwise} \end{array} \right., \forall j = 1,2, \ldots, n
\]  

(1)

The external arrival rate at node \( j \), \( \lambda_{0j} \), is the sum of all arrival rates of classes whose first node is \( j \). And, the flow rate from \( i \) to \( j \) is calculated by (2); the flow from \( i \) out of the network is calculated by (3).

\[
\lambda_{ij} = \sum_{r=1}^{k} (\lambda_i^r \times p_{ij}^r) \quad \forall i, j = 1,2, \ldots, n
\]  

(2)

\[
\lambda_{i0} = \sum_{r=1}^{k} (\lambda_i^r \times p_{i0}^r) \quad \forall i = 1,2, \ldots, n
\]  

(3)

Using equations 2 and 3 the overall routing matrix is obtained by (4).

\[
P_{ij} = \frac{\lambda_{ij}}{\lambda_{0i} + \sum_{l=1}^{n} \lambda_{il}} \quad \forall i, j = 1,2, \ldots, n
\]  

(4)

The combined mean and the SCV of service-time of each node are obtained by (5)-(6).

\[
\tau_j = \frac{\sum_{r=1}^{k} (\tau_j^r \times \lambda_j^r)}{\lambda_j}, \quad \forall j = 1,2, \ldots, n
\]  

(5)

\[
\tau_j (c_{ij}^2 + 1) = \frac{\sum_{r=1}^{k} ((\tau_j^r)^2 \times \lambda_j^r \times (c_{ij}^2 + 1))}{\lambda_j}, \quad \forall j = 1,2, \ldots, n
\]  

(6)

3.7 SERVICE TIME CALCULATIONS

The general view of SOQN of the AVS/RS is illustrated in Figure 2. According to that figure there are two types of queues in the system, one is the vehicle queue and the other is the lift queue. Transactions arriving to the system first enter the vehicle queue, then the lift queue. In the storage transactions, the vehicles travel to the I/O point to pick up the load. In the retrieval transactions, the vehicles travel to the load’s location to retrieve it. For both transactions, the vehicles use a lift if it must travel to a tier other than its. In Figure 2, the server \( VT_1 \) corresponds to the vehicle’s horizontal travel from its current position to the lift’s location. \( LT \) corresponds to the lift’s travel. \( VT_2 \) corresponds to the vehicle’s horizontal travel to complete a storage or retrieval. In other words, it is the travel from vehicle’s current position to the storage/retrieval position after it reaches the destination tier, including load/unload activities. In the real AVS/RS system, the vehicle is seized and not released until it completes the entire storage or retrieval. \( VT_1 \) and \( VT_2 \) are servers used to capture vehicle travel times and thus are not real servers. Therefore, dummy vehicle queues are shown before \( VT_1 \) and \( VT_2 \) in Figure 2.

We also consider a synchronization station after the external queue where transactions and vehicles synchronize. After a vehicle completes storage or retrieval it becomes free and returns to the vehicle pool to be used by the waiting transaction.

Each scenario has its own route and service times at each node. For instance, because the vehicles are at the I/O point in the \( S_4 \) and \( S_6 \) of storage scenarios, the vehicles will not visit \( VT_1 \). In addition, in the \( S_3 \) and \( S_5 \) of retrieval scenarios, the transactions will go to \( VT_2 \) directly after seizing the vehicle.
Consequently, after the derivation of service times of VT₁, LT, and VT₂ of each scenario and combination of them, the mean and the squared coefficient of variation SCV of general service times of all nodes and the routing probabilities P₁-P₇ are obtained as below:

\[ P₁ = 0.464, \quad P₂ = 0.5, \quad P₃ = 0.036, \quad P₄ = 0.659, \quad P₅ = 0.341, \quad P₆ = 0.5, \quad P₇ = 0.5\]

\[ 𝜏₁ = 0.511 \text{ min.}, \quad c₁^2 = 0.115, \quad 𝜏₂ = 0.413 \text{ min.}, \quad c₂^2 = 0.233, \quad 𝜏₃ = 0.756 \text{ min.}, \quad c₃^2 = 0.065.\]

After verifying the VT₁, LT, and VT₂ values using simulation, we complete further analyses and solve the Figure 2 network using Avi-Itzhak’s [10] approximation method:

1. First, we transform the SOQN into a closed queuing network (CQN) except the synchronization station. Then, we identify the synchronization station as the first station where transactions may have to wait for a vehicle.

2. Second, we solve the CQN station using Marie’s technique, and obtain the load-dependent throughput rates. Marie has presented an efficient technique for the approximate analysis of general CQN. The basic idea is to approximate the performance of the general network by the performance of a product-form closed queuing network. It provides satisfactory results for a wide range of queuing networks [11].

3. Third, we replace the synchronization station by a load-dependent exponential server with the service rates obtained in step 2.

4. Finally, we find the mean number of transactions in the external queue and network by considering synchronization station in isolation and by solving the birth and death process (M/M/1) that describes its behavior.

**4. CONCLUSION**

In this paper an analytical model of AVS/RS system is presented. We model the AVS/RS with a SOQN approach. First, the mean and SCV of service times are derived using probabilities of pre-defined scenarios of AVS/RS. Second, the AVS/RS system is modeled as a SOQN by considering a synchronization station in the network. Then, the network is solved using a four stepped iterative method as in Avi-Itzhak (see section 3.3). To obtain the load-dependent throughput rates of the CQN, Marie’s approximation is used [11]. Last, the synchronization station is replaced by a load-dependent exponential server and is solved as a birth and death system. The performance measures are obtained for the mean number of transactions in the external queue and network.

ABSTRACT

The calibration of a three-dimensional digitizer is a very important issue to take into consideration that good quality, reliability, accuracy and high repeatability are the features which such a good digitizer is expected to have. The aim of this paper is to propose a new method for the calibration of a 3-D laser scanner, mainly for robotic applications. The acquisition system consists of a laser emitter and a webcam with fixed relative positions. In addition, a cylindrical lens is provided with the laser housing so that it is capable to project a plane light. An optical filter was also used in order to segment the laser stripe from the rest of the scene. For the calibration procedure it was used a digital micrometer that move a target with known dimensions. The calibration method is based on the modeling of the geometrical relationship between the 3-D coordinates of the laser stripe on the target and its digital coordinates in the image plane. By this method it is possible to calibrate the intrinsic parameters of the video system, the position of the image plane and the laser plane in a given frame, all in the same time.

1. INTRODUCTION

Calibration is basic requirement in multi-sensor platforms where data needs to represented in a common reference frame for the purpose of analysis and data fusion. On platforms where a camera provides intensity information in the form of an image and a laser supplies depth information in the form of a set of 3-D points, external calibration allows reprojection of the 3-D points from the laser coordinate frame to the 2-D coordinate frame of the image. The process of external calibration is often poorly documented and is almost always notoriously laborious. It usually involves some modification of the scene in the form of markers with features visible by both the camera and the laser. These features are often in the form of edges or corners extracted from the laser data with considerable user intervention. In procedures where the features are edges or corners, the quality of the final estimates is dependent on the accuracy by which features can be localized and so requires the ability to obtain laser data at very high resolution.

The procedure proposed in this document uses no more than the same checkerboard calibration target commonly used for internal calibration of the camera. An interactive GUI allows the user to acquire the images of laser on a target that can move along camera optical axis, by means of a digital micrometer. A robust fitting procedure fits geometrical relationship between the 3-D coordinates of the laser stripe on the target and its digital coordinates in the image plane, based on triangulation principle.

By this method it is possible to calibrate the intrinsic parameters of the video system, the position of the image plane and the laser plane in a given frame, all in the same time.
2. 3-D RECONSTRUCTION: PRINCIPLE OF OPERATION

There are many methods in order to reconstruct the object shape by means of videos or images [1]. In this paper is described a system, that consists of a linear laser emitter and a webcam, and uses triangulation principle applied to a scanning belt on object surface [2].

Camera observes the intersection between laser and object: laser line points in image frame, are the intersections between image plane and optical rays that pass through the intersection points between laser and object. By means of a transformation matrix, it is possible to express the image frame coordinates, in pixel, in a local reference frame. In figure 1 a) is shown a scheme of scanning system: \{W\} is local reference frame, \{I\} is image frame with coordinates system \{u,v\}, and \{L\} is laser frame. \{L2\} is laser plane that contains laser knife and scanning belt on the surface of object, and it coincides with \((x,y)\) plane of laser frame \{L\}, [3].

![Figure 1: reference frames](image)

Starting from the coordinates in pixel \((u,v)\), in image frame, it is possible to write the coordinates of the scanning belt on the object surface, in camera frame by means of equation (1). Camera frame is located in camera focal point figure 1 b).

\[
\begin{bmatrix}
    x_c \\
    y_c \\
    z_c \\
    1
\end{bmatrix} =
\begin{bmatrix}
    \delta_x & 0 & 0 & -\delta_x u_0 \\
    0 & \delta_y & 0 & -\delta_y v_0 \\
    0 & 0 & f & 0 \\
    0 & 0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
    u \\
    v \\
    0 \\
    1
\end{bmatrix}
\]

(1)

With:
- \((u_0,v_0)\): image frame coordinates of focal point projection in image plane;
- \((\delta_x, \delta_y)\): physical dimension of sensor pixel along direction u and v;
- \(f\): focal length.

It is possible to write the expression of the optical beam of a generic point in the image frame, that can be identified by means of parameter \(t\).

\[
\begin{align*}
    x_c &= (u-u_0)\delta_x t \\
    y_c &= (v-v_0)\delta_y t \\
    z_c &= ft
\end{align*}
\]

(2)

Laser frame \{L\} is rotated and translated respect to camera frame, the steps and their sequence are:

1. Translation \(\Delta x_{lc}\) along axis \(x_c\);
II. Translation $\Delta y_k$ along axis $y_c$;

III. Translation $\Delta z_k$ along axis $z_c$;

IV. rotation $\phi_k$ around axis $z_c$;

V. rotation $\theta_k$ around axis $y_c$;

VI. rotation $\psi_k$ around axis $x_c$;

Hence in equation (3) the transformation matrix between laser frame and camera frame is:

$$\begin{bmatrix} T \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(\psi_k) & -\sin(\psi_k) & 0 \\ 0 & \sin(\psi_k) & \cos(\psi_k) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos(\theta_k) & 0 & \sin(\theta_k) & 0 \\ 0 & 1 & 0 & 0 \\ -\sin(\theta_k) & 0 & \cos(\theta_k) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

(3)

Laser plane $\{L2\}$ coincides with $(x,y)$ plane of laser frame $\{L\}$, so it contains three points:

$$\{p\}_l = (0,0,0,1)^T; \{q\}_l = (1,0,0,1)^T; \{r\}_l = (0,0,1,1)^T.$$

(4)

In camera frame:

$$\{p\}_c = \begin{bmatrix} x_c - p_x \\ y_c - p_y \\ z_c - p_z \end{bmatrix}; \{q\}_c = \begin{bmatrix} q_x - p_x \\ q_y - p_y \\ q_z - p_z \end{bmatrix}; \{r\}_c = \begin{bmatrix} r_x - p_x \\ r_y - p_y \\ r_z - p_z \end{bmatrix};$$

$$\begin{bmatrix} x_c - p_x \\ y_c - p_y \\ z_c - p_z \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \cos(\theta_y) & 0 & \sin(\theta_y) & 0 \\ 0 & 1 & 0 & 0 \\ -\sin(\theta_y) & 0 & \cos(\theta_y) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_l \\ y_l \\ z_l \end{bmatrix} - \begin{bmatrix} \Delta x_k \\ 0 \\ 0 \end{bmatrix}.$$

(5)

It is possible to obtain laser plane equation in camera frame, solving equation (6) in $x_c$, $y_c$ and $z_c$:

$$\begin{vmatrix} x_c - p_x & y_c - p_y & z_c - p_z \\ q_x - p_x & q_y - p_y & q_z - p_z \\ r_x - p_x & r_y - p_y & r_z - p_z \end{vmatrix} = 0.$$

(6)

If it is:

$$M_x = \begin{vmatrix} q_x - p_x & q_y - p_y \\ r_x - p_x & r_y - p_y \end{vmatrix}; M_y = \begin{vmatrix} q_x - p_x & q_z - p_z \\ r_x - p_x & r_z - p_z \end{vmatrix}; M_z = \begin{vmatrix} q_y - p_y & q_z - p_z \\ r_y - p_y & r_z - p_z \end{vmatrix};$$

$L_2$ equation in camera frame, is:

$$(x_c - p_x)M_x - (y_c - p_y)M_y + (z_c - p_z)M_z = 0.$$

(7)

It is possible to evaluate coordinates $x_c$, $y_c$, $z_c$ in camera frame, solving system (8) with unknown $t$:

$$\begin{cases} x_c = (u - u_0)\delta_x t \\ y_c = (v - v_0)\delta_y t \\ z_c = ft \\ ((x_c - p_x)M_x - (y_c - p_y)M_y + (z_c - p_z)M_z = 0 \end{cases}.$$
The solution is:

\[ t = \frac{p_xM_x - p_yM_z + p_zM_y}{(u - u_o)\delta_xM_x - (v - v_o)\delta_yM_y + fM_z} \]  

(9)

Equation (9) permits to compute in the camera frame, the points coordinates of the scanning belt on the object surfaces, starting to its image coordinates \((u,v)\). In this way it is possible to do a 3-D objects reconstruction by means of a laser knife.

### 3. DETECTION OF THE LASER PATH ON THE TARGET

A very important step for 3-D reconstruction is image elaboration for the laser path on the target [4, 5, 6], the latter is shown in figure 2.

![Figure 2: laser path image](image)

Image elaboration procedure permits to user to choose some image points of laser line, in order to identify three principal colours (Red, Green, and Blue) of laser line, figure 3.

![Figure 3: laser line RGB representation](image)

With mean values of scanning belt principal colours, it is possible to define a brightness coefficient of the laser line, according to relation (10):

\[ s = \frac{\text{max}(\text{mean}(R),\text{mean}(G),\text{mean}(B)) + \text{min}(\text{mean}(R),\text{mean}(G),\text{mean}(B))}{2} \]  

(10)

By means of relation (11), an intensity analysis is carried out on RGB image.

\[ L(u,v) = \frac{\text{max}(R,G,B) + \text{min}(R,G,B)}{2} \]  

(11)

By equation (11), the matrix that contains the three layers of RGB image, is transformed in a matrix \(L\), that represents image intensity. This matrix represents same initial image, but it gives information only about luminous intensity in each image pixel, and so it is a grayscale expression of initial RGB image, figure 4 a) and b).
A Method for the Calibration of a 3-D Laser Scanner

With relation (12), it is possible to define a logical matrix $I_b$. Matrix $I_b$ indicates pixels of matrix $L$ with a brightness in a range of 15% brightness coefficient $s$.

$$I_b(u, v) = \begin{cases} 1 & \text{if } \frac{0.85}{s} \leq L(u, v) \leq \frac{1.15}{s} \\ 0 & \text{otherwise} \end{cases}$$  \hspace{1cm} (12)$$

In figure 4 c), matrix $I_b$ is shown.

In matrix $I_b$, the scanning belt on the object surface (see fig. 5) is represented by means of the pixel value one. The area of the laser path in the image plane depends on the real dimension of laser beam and on external factors such as: reflection phenomena, inclination of object surfaces.

3-D reconstruction procedure is based on triangulation principle and it doesn’t consider the laser beam thickness, so it is necessary to associate a line to the image of scanning belt.

Since the laser path in the image plane is rather horizontal, a geometrical mean is computed on, on the columns of the matrix $I_b$, that is to say: in the opposite direction to wider extension of the laser path in the image. This is shown in equation (13).

$$\Omega := \{u, v\}; \Omega := \{\bar{u}, \bar{v}\} \Rightarrow \bar{u} = \frac{\sum_{u, v \in \Omega} u I_b(u, v)}{\sum_{u, v \in \Omega} I_b(u, v)} \neq \infty, \bar{v} = \nu : \sum_{u, v \in \Omega} I_b(u, v) \neq 0$$  \hspace{1cm} (13)

Then a matrix $h_b$ is also defined as follows:

$$h_b(u, v) = \begin{cases} 1 & \text{if } (u, v) \in \Omega \\ 0 & \text{otherwise} \end{cases} \hspace{1cm} (14)$$

Matrix $h_b$ is hence a logical matrix with same dimension of $I_b$ in which that represents laser image like a line, figure 6. This line is centre line of scanning belt on object surface in image.
The set of transformations (11), (12) and (13) represents the image elaboration, that is necessary to identify a laser line in image. The points of this line are used in 3-D reconstruction procedure.

4. CALIBRATION SYSTEM

It is necessary to identify all model parameters in order to obtain a good 3-D reconstruction. Calibration is a basic procedure for the data analysis [3, 5, 7]. For this reason, it was developed a calibration procedure for a classic laser scanner module.

The laser scanner module is composed by a web-cam with resolution 640x480 pixel and a linear laser. The calibration test rig is realized with a guide on which is fixed the laser scanner module and a digital micrometer with a target, figure 7 a).

A fixed frame $O_{xfyfz}$ has origin in a vertex of the rectangular target with dimension $a=68$ mm and $b=74.5$ mm, like it is shown in figure 7 b). Target movements are indicated with $\Delta z_{bf}$.

In figure 8 some steps of calibration procedure are shown.

Calibration procedure is based on a set of images, taken with the target placed in different positions respect to the laser scanner module. A least square optimization allows to identify all parameters. In figure 9 are shown 20 images used for calibration, of scanning belt, with 20 different $\Delta z_{bf}$. 
A Method for the Calibration of a 3-D Laser Scanner

The aim of calibration procedure is to obtain the parameters that define the relation between laser frame $L_xL_yL_z$ and camera frame $O_xO_yO_z$, figure 1.

In every calibration step, it is possible to define transformation matrix between fixed frame $O_xO_yO_z$ and target frame:

$$\begin{bmatrix} T_i \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0; 0 & 1 & 0; 0 & 0 & 1 - \Delta \theta; 0 & 0 & 0 \end{bmatrix}$$

(13)

The transformation matrix between fixed frame $O_xO_yO_z$ and camera frame $O_xO_yO_z$ can be obtained analogous to matrix $[T_f]$, and it is a function of six parameters:

$$[T_i] = f(\Delta x, \Delta y, \Delta z, \psi, \theta, \phi) = f(\pi_{cf})$$

(14)

with $\pi_{cf}$ set of parameter of transformation $[T_c]$.

Equation (3) can be written as:

$$[T_i] = g(\Delta x, \Delta y, \Delta z, \psi, \theta, \phi) = f(\pi_{cf})$$

(15)

with $\pi_{cf}$ set of parameter of transformation $[T_c]$.

For each step of the calibration procedure it is possible to evaluate the coordinates of the points of the laser line in the camera frame, according to equations (5) and (13):

$$[\bar{x}, \bar{y}, \bar{z}]^T = f(\pi_{cf}, f) \cdot [\bar{u}, \bar{v}, 0, 1]^T$$

(16)

By means of equation (14), it is possible to write:

$$[\bar{x}, \bar{y}, \bar{z}]^T = [T_i]^{-1} \cdot [\bar{x}, \bar{y}, \bar{z}, 1]^T = [T_i]^{-1} \cdot f(\pi_{cf}, f) \cdot [\bar{u}, \bar{v}, 0, 1]^T = \alpha(\pi_{cf}, \pi_{lc}, f) \cdot [\bar{u}, \bar{v}, 0, 1]^T$$

(17)

The optimization problem can be defined as:

$$\min_{\rho \in R} F(\rho)$$

(18)

$F(\rho)$ is a vectorial function defined as:

$$F(\rho) = \{(\pi_{cf}^{(i)} - \pi_{cf}^{(j)}) - (\Delta \theta^{(i)} - \Delta \theta^{(j)}), \min(x_{cf}^{(i)}), \max(x_{cf}^{(i)}) - \alpha, \max(y_{cf}^{(i)}) - \min(y_{cf}^{(i)}), \max(y_{cf}^{(i)}) - \min(y_{cf}^{(i)}), \min(z_{cf}^{(i)})\}^T$$

(19)

With a least square optimization, the unknown parameters of set $[\pi_{cf}, \pi_{lc}, f]$ are identified.

An interactive GUI was developed to allow the user to acquire images, to execute optimization and to verify the results.
In figure 10, a graphical result of calibration is shown: it is possible to observe the camera frame position, the laser beam (represented by the quadrilateral on the left), and the 3-D reconstructions of scanning beam on target surface, for each image used in the calibration procedure.

Figure 10: calibration results

5. CONCLUSION

A method for calibration of a 3-D laser scanner has been presented. The procedure is absolutely non-invasive since it does not involve any modification of the scene; in fact no markers with features visible by both the camera and the laser, or any other device, are required.

The method essentially uses a laser emitter and a webcam with fixed relative positions. A cylindrical lens and an optical filter are also provided; the first one is in order to project a plane light, while the second one was used to segment the laser stripe from the rest of the scene. The calibration method is based on the modeling of the geometrical relationship between the 3-D coordinates of the laser stripe on the target and its digital coordinates in the image plane. By this method it is possible to calibrate the intrinsic parameters of the video system, the position of the image plane and the laser plane in a given frame, all in the same time.

University of Naples “Federico II"
Naples, via Claudio 21, 80125 ITALY

ABSTRACT

The first results of a new method for real time shape acquisition with a laser scanner are presented. The new method is essentially based on the use of a laser beam and a web cam. A digital filter parameters identification was studied for the laser line detection in the image. After this a model for the reconstruction in real time of the laser line in the space was developed. The first test rig was just conceived to validate the method, hence no high resolution cameras were adopted. Nevertheless the tests have showed encouraging results.

Tests were made on both plane and non plane surfaces. First of all it was confirmed that it is possible to calibrate the intrinsic parameters of the video system, the position of the image plane and the laser plane in a given frame, all in the same time. Moreover the surface shapes were recognized and recorded with an appreciable accuracy. The tests also showed that the proposed method can be used for robotic applications such as robotic kinematic calibration and 3D surfaces recognition and recording. For this last purpose the test rig is fitted on a robot arm that permits to the scanner device to ‘observe’ the 3D object from different and known positions.

1. INTRODUCTION

Laser scanning range sensors are widely used for high-precision, high-density three-dimensional (3D) reconstruction and inspection of the surface of physical objects [1]. The process typically involves planning a set of views, physically altering the relative object-sensor pose, taking scans, registering the acquired geometric data in a common coordinate frame of reference, and finally integrating range images into a non-redundant model [2]. Efficiencies could be achieved by automating or semi-automation this process.

The first aim of the research was to study an analysis procedure to elaborate image of laser in order to obtain 3-D object reconstruction, after an opportune system calibration. The technique has been automated by developing an interactive GUI to acquire and to elaborate data.

Reverse engineering is concerned with the problem of creating computer aided design (CAD) models of real objects by interpreting point data measured from their surfaces [2, 3]. For complex objects, it is important that the measuring device is free to move along arbitrary paths and make its measurements from suitable directions. This paper shows how a standard industrial robot with a laser profile scanner can be used to achieve that freedom. The system is planned to be part of a future automatic system for the Reverse Engineering of unknown objects. The system was designed around a test rig developed in our department by means of a commercial linear laser and a common web-cam; this system is moved by a revolute robotic arm.

2. EXPERIMENTAL PLATFORM

2.1 LASER SCANNER MODULE

Our rig, is based on a laser profile, that essentially consists in a line laser and a camera. The laser beam defines a “laser plane” and the part of the laser plane that lies in the image view of the camera is denoted the “scanning window”, figure 1. After an opportune system calibration it is possible to find a relation that permits to compute in the camera frame, the points coordinates of the scanning belt on the object surfaces, starting to its image coordinates. In this way it is possible to do a 3-D objects reconstruction by means of a laser beam.

The laser scanner device was realized by assembling a commercial linear laser and a common web-cam. The calibration operation provides to evaluate all parameters that are necessary to define the scanner module model.

2.2 ROBOT

In order to optimize the accuracy of the reconstruction resulting model, scanning should be adapted to the shape of the object. One way to do that is to use an industrial robot to move a laser profile scanner along curved paths.

The scanner laser module was mounted on a revolute robot with three d.o.f., designed and assembled in our Department, figure 2.
The robot serves as a measuring device to determine the scanning window position and orientation in 3D for each camera picture, with a great precision. All scan profiles captured during a scan sequence must be mapped to a common 3D coordinate system, and to do this, positional information from the robot were used [4]. Figure 3 shows the equipment at work.

The authors have developed a solution where the robot controller and scanner software work separately during a scan sequence that will be described in the following paragraphs.

3. EQUATIONS OF THE MODEL

3.1 MODEL OF THE LASER SCANNER

Camera observes the intersection between laser and object: laser line points in image frame, are the intersections between image plane and optical rays that pass trough intersection points between laser and object. In the figure 4 is shown a sketch of the laser-camera system.

For each point in the image plane, under the assumption of the pin hole camera model, it’s possible to write the follow relationship:

\[
\begin{align*}
  x_c &= (u - u_o) \delta v t \\
  y_c &= (v - v_o) \delta u t \\
  z_c &= ft
\end{align*}
\]  

(1)
With:

\((u_0,v_0)\): image frame coordinates of focal point projection in image plane;

\((\delta_u, \delta_v)\): fisical dimension of sensor pixel along direction \(u\) and \(v\);

\(f\): focal length.

For all the points in the image plane that represent the laser path namely the condition that they must belong to the laser plane as shown following:

\[
\begin{align*}
\begin{cases}
    x_v = \frac{(u - u_0) \delta_u z_v}{f}, \\
    y_v = \frac{(v - v_0) \delta_v z_v}{f}, \\
    Ax_v + By_v + Cz_v + D = 0
\end{cases}
\end{align*}
\]  

(2)

Where, considering a generic point \(\vec{p}_v\) in the laser plane and a vector \(\vec{v}\) orthogonal to the laser plane, whose components are \(A, B\) and \(C\), \(D\) is defined as follow:

\[
\vec{p}_v = \begin{bmatrix} x_v \\ y_v \\ z_v \end{bmatrix}, \quad \vec{v} = \begin{bmatrix} 1 \\ A \\ B \end{bmatrix}, \quad D = -A\vec{x} - B\vec{y} - C\vec{z} 
\]  

(3)

From the system (2) it’s possible to write the coordinates of the points of the laser path in the camera frame:

\[
\begin{align*}
\begin{cases}
    x_v = \frac{(u - u_0) \delta_u z_v}{f}, \\
    y_v = \frac{(v - v_0) \delta_v z_v}{f}, \\
    z_v = \frac{-Df}{Af (u - u_0) \delta_u + Bf (v - v_0) \delta_v + Cf}
\end{cases}
\end{align*}
\]  

(4)

Equations (4) permits to compute in the camera frame, the points coordinates of the scanning belt on the object surfaces, starting to its image coordinates \((u,v)\), in pixel. In this way it is possible to do a 3-D objects reconstruction by means of a laser knife.

3.2 Model of the Laser Scanner on the Robot

When the laser scanner module is installed on the robot, figure 3, it is possible to use positional information from robot to determine the scanning window position and orientation in 3D.

Defining \([DH]\) as the transformation matrix between coordinates in the robot base frame \(0\) (the fixed one) and those in frame \(3\) (the one of the last link), figure 5, for the coordinates of a generic point \(P\) exists this relationship:

\[
\begin{bmatrix} P^0 \end{bmatrix} = [DH] \cdot \begin{bmatrix} P^3 \end{bmatrix}
\]  

(5)

The matrix \([DH]\) depends on 9 constant kinematic structure parameters, that are known, and 3 variable joints position parameters that are measurable by means of robot control system.
Knowing the transformation matrix $[^{T_i}T]$ between the camera frame and the frame of the robot last link, it’s possible to obtain a transformation matrix between the camera frame and the frame 0, figure 6.

$$\{P\}_c = \left[^{T_i}T\right] \cdot \left[^{DH}D\right]^{-1} \cdot \{P\}_0$$  \hfill (6)

By means of the equations (4) and (6), the relationship between image coordinates $(u,v)$ of the laser path and its coordinates in the robot base frame 0, is defined. By means of these equations, it is possible to reconstruct the 3D points in the robot base frame, of the intersection between the laser line and the object.

Robot positioning errors do not influence the 3D reconstruction, because each image is acquired and elaborated in a real robot position, that is known by means of robot encoders [5].

4. DATA CAPTURE AND REGISTRATION

The scanner video camera captures profiles from the surface of the object as 2D coordinates in the laser plane. During a scan sequence the laser scanner module is moved in order to capture object images from different sides and with different angles-shot according to the shape of the object.

In Matlab, an interactive GUI was developed in order to allows users to acquire and to elaborate data, figure 7. For each camera picture, along the scan path, the scanner derives a scan profile built up of point coordinates, in real-time.

The first step present in the GUI is the load of the calibration parameters that are composed by the laser scanner parameters and the matrix $[^{T_i}T]$. The second step is to filter the pixels of the laser path from the image, to do this, there are some regulations: the identification of the intensity of selected pixels, the calculus of the threshold and other regulations of the camera settings. The third step is to write the 3 joint position parameters of the robot in the window “position”, after this, clicking on the button “Image” the software save all the information, necessary for
the reconstruction, in the workspace of the Matlab. Clicking on the button “3D generation” the software calculates the 3D positions of the laser path in the robot base frame, and the result is shown on the GUI window.

When the scanning procedure is completed, the user can save images and relative robot position information in a file, save the cloud of points represent the surface of the test object and export the surface information in a file format that permits to load the data from the CAD software “CATIA”.

Besides it’s possible to load image information from a preview scanning procedure, this is useful for reconstruct the same laser path information using different calibration parameters.

![Figura 7:developed software](image)

5. EXPERIMENTAL RESULTS

The system has been tested before in a fixed robot position, to verify calibration and reconstruction procedures, then the shape of some components, was defined using robot to move laser scanner module. The test objects are shown in the figure 8.

![Figure 8: test objects](image)
In the figure 9 and 10 it’s possible to see a step of the procedure with the final results for the two test specimens.

Figure 9: elaboration procedure of the first test specimen

Figure 10: elaboration procedure of the second test specimen

With the use of the software CATIA it was possible to build the surface of the two test objects, in this way it was obtained the CAD model, this step of the 3D reconstruction method is a real reverse engineering application. The routine “Digitized shape editor” of the “CATIA” addresses digitalized data import, clean up, tessellation, cross sections, character line, shape and quality checking. In the figure 11 and 12 are shown the comparisons between the clouds of points and the respective surfaces for each object.

Figure 11: first test specimen results
6. CONCLUSION

The first results of a new method for real time shape acquisition with a laser scanner are presented. Although the test rig has been conceived just to validate the method (hence no high resolution cameras were adopted), the tests have showed encouraging results.

The test results also confirmed that it is possible to calibrate the intrinsic parameters of the video system, the position of the image plane and the laser plane in a given frame, all in the same time. Moreover the surface shapes were recognized and recorded with an appreciable accuracy.

The tests also showed that the proposed method can be used for robotic applications such as robotic kinematic calibration and 3D surfaces recognition and recording. For this last purpose the test rig was fitted on a robot arm that permitted to the scanner device to ‘observe’ the 3D object from different and known position.

Further tests will concern a detailed analysis of the sources of errors and the verification of the accuracy achieved. As far as the latter aspect is concerned, the authors believe that a better system for tracking the position of the robot arm could enhance accuracy.

Finally, the authors would like to point out that the solution proposed is relatively low cost, scalable and flexible. It is also suitable for applications other than RE, like robot control or inspection.

Development of a Modular, Reconfigurable End Effector for the Plastics Industry: A Case Study

Michael A. Saliba*, Andrew Vella Zarb, and Jonathan C. Borg

Department of Industrial and Manufacturing Engineering
University of Malta
Msida, MSD 2080, Malta

ABSTRACT

A common problem in large manufacturing companies in the plastics industry is the need to handle mass produced injection-moulded items in the presence of a high degree of variety between batches. In this work, we address a problem being faced by such a company, where different batches of freshly-produced units need to be unloaded from the injection moulding machines. The products need to be grasped and relocated, and the runners disposed of. The number of identical units produced simultaneously by each single mould varies between two and sixteen, and the company makes use of around four hundred different moulds. We have developed a single modular end effector that can be easily reconfigured for the different moulds used by the company, and that also caters for future product designs. We present the detailed design of the new solution, including a function analysis derived from the existing process, a new product design specification, and a quality function deployment exercise. This is followed by the generation of a number of conceptual solutions to the problem, and the evaluation of the alternative concepts using morphological charts, failure mode and effect analysis, and a decision matrix. We present also a detailed embodiment design of the selected concept, and report on prototype development, evaluation and testing. Finally we discuss potential improvements through the use of the new system, and extrapolate the results of this work to more general applications where an end effector is required to carry out simultaneously several different but well defined functions in the presence of high variety.

1. INTRODUCTION

Manufacturing automation systems have traditionally been categorised into three distinct types, these being fixed, programmable, and flexible (see, for example, [1]). Fixed automation refers to a system that is custom designed for the production of a particular product, and is indicated where the production volume is high but where the product has little or no variety. Such a system has a number of benefits due to its dedicated nature, including relatively low cost and simplicity, however it has the major potential drawback of becoming obsolete if and when the product is discontinued. Programmable automation refers to a system in which the sequence of operations and motion parameters can be changed to accommodate different product batches, and is indicated in situations where production volumes are low but where there is relatively high product variety. Programmable automation systems are typically computerised numerically controlled (CNC) machines or industrial robots. While offering the significant advantage of being applicable to a variety of products, these systems normally require a high investment cost, and normally require a significant amount of set-up and programming time between batches of different products. Flexible automation refers to a system that can handle a variety of products without set-up or reprogramming. Such systems are widely regarded as representing an ultimate achievement in automation, however they are not without drawbacks. Generally, they are relatively complex systems that come at a substantial cost, and moreover the amount of product variety that they can process is often quite limited.

Today’s market is characterised by tough competition that continually forces manufacturers to push down their costs, coupled with a discerning customer who constantly demands a higher level of variety. This scenario has led to the search for new automation systems that combine advantages of the three traditional approaches, while mitigating the disadvantages of each. The ideal automation system would be cheap and simple to implement, while at the same time would be able to handle a high degree of variety with minimal set-up time between batches of different...
products. This search has led to the development of a new paradigm in manufacturing automation, that of reconfigurable automation [2], [3], [4], [5], [6]. The basic concept of this approach is to develop an automation system that is very modular in nature, and where the constituent modules can be quickly interchanged, exchanged, or otherwise reconfigured to handle different products. Once the two fundamental problems of module definition and of module interfacing have been solved, these systems can become quite inexpensive and simple to implement, have the capability to handle a significant amount of variety, and can be reconfigured (normally manually) relatively fast.

A very common requirement in manufacturing automation systems is that of grasping and handling objects, and as such, significant effort is very often made to maximise the effectiveness of this function within the automation system (e.g., [7], [8]). Where it is required to find a relatively low cost solution to dealing with the gripping of objects in the presence of variety, the use of a reconfigurable gripping device may be indicated. This is often done by developing a gripper in which the positions of some or all of the fingers can be adjusted to accommodate each particular batch of objects before the start of each production run (e.g. [9], [10]).

In this work, we address a handling problem related to the plastics injection moulding industry, namely the transfer of freshly produced parts from a mould to a conveyor, on which the parts later move for further processing. The issue is addressed in the context of an actual case study, in which a company is seeking to improve an already automated process. As shall be seen below, the problem at hand has a number of distinctive features. Apart from a high degree of variation in part size and shape (approximately four hundred different products) that need to be handled, the number and positions of idential parts manufactured simultaneously within each mould also differs. Furthermore, in addition to grasping the parts, the parts handling device has to cut and dispose of the runners and sprues associated with the injection moulding process. The grasped parts need to be released on to the conveyor in a highly ordered manner, in order to be ready for further automated processing. The main general objectives that need to be achieved are a reduction in the cost associated with the development and set-up of the gripping device whenever a new product is introduced by the company; and a reduction in the required storage space for the gripping devices and associated sub-components that are not in use. For the reasons indicated above, the approach selected to solve this problem is the design and development of a modular, reconfigurable end effector.

2. PROBLEM DEFINITION

2.1. THE COMPANY

The company involved in this work is privately-owned and deals with the manufacture of high quality plastic packaging. The plastic products go from raw material to the finished packaging product in-house. The cases and containers produced are then sold to client companies that complete the production process and distribute the products to retailers, for eventual sale to the end users. All the cases produced by the company have to meet very high standards of quality on both an aesthetic and a functional basis. To produce such high quality products, the production equipment used is centred on quality, and the margin of acceptable defects is very small.

To retain its competitive edge the company is always seeking to improve its manufacturing system. These improvements can range from the installation of new machinery to simply altering a sequence of production operations using the current installation. These changes can often work out to be costly and then become counterproductive as the product price may increase, thus reducing the economic competitiveness. However product quality can be improved without increasing cost, by investing in automation and lean manufacturing techniques. These techniques strive to reduce waste and thus increase profitability by reducing the overall product cost.

In light of this, the company is constantly seeking to reduce waste (both material and time) in various stages of the production operations. This is what has led to the formulation of this project.

2.2. THE CURRENT PROCESS

The operation under consideration involves the unloading of the injection moulded parts from the open mould, the disposal of the runners, and the transfer of the parts to a conveyor system. This operation is already automated using Cartesian robots, but the company has a different end effector associated with each mould, to grasp and relocate the units and to cut and dispose of the runners. The number of identical units produced simultaneously by each single mould varies between two and sixteen. The company makes use of around four hundred customized end effectors, with an associated penalty in storage, handling, and set-up costs. The company designs and develops a
new end effector whenever a new product is commissioned. The maximum combined weight of the parts to be transferred is of about 3N.

An example of an end effector that is currently used for this operation is shown in Figure 1(a). The end effectors, or robot plates, make use of vacuum grippers (Figure 2(b)) to grasp the moulded parts, and jaw grippers (Figure 1(c)) to grasp and snap off the runners. For the example given, the mould produces four units per cycle, with the positions of the finished units within the open mould corresponding to the positions of the four vacuum grippers on the robot plate, which would have been custom built for this particular mould.

![Figure 1: (a) Robot plate, (b) Vacuum grippers, and (c) Jaw gripper](a) (b) (c)

The work is batch oriented. This means that a particular product is produced for a limited period of time to fulfill a customer’s needs. Once the pre-ordered number of products have been produced, the product is discontinued for an amount of time which may vary. Every time a batch has been completed, the tooling used is removed from the injection machine, the particular robot plate is removed from the robot wrist mounting plate, and the controller programs are saved and removed from the controller. Once the injection machine is needed for a new batch (of the same product or even different products) the tool is once again mounted on the injection machine platen if already manufactured, its respective robot plate is mounted or custom made, and the relevant controller program is either re-loaded or written from scratch.

Every mould tool requires a particular robot plate. The number of mould tools used already exceeds four hundred, and new products are continually developed. The customized robot plates are not only expensive to produce, but are also expensive to store due to the large number of plates kept.

### 2.3 Function Analysis

The parts are gripped from the open mould, in the vertical position. In this position the retaining force of the vacuum grippers is at its lowest, being exposed to a shearing force by the weight of the part. The robot plate is then raised above the open mould, still in the vertical position. Once clear of the mould, the wrist mounting plate then rotates downwards, thus positioning the gripped parts directly below the robot plate. Here the vacuum gripper retaining force is higher since the weight of the parts is acting directly against the vacuum force applied. A vertical and horizontal translation by the robot then positions the robot plate over a disposal bin. Here the jaw grippers are opened, releasing the runners which fall into a disposal bin. The robot plate is then translated horizontally and over the conveyor belt. Once in position, the robot plate is then lowered, gently placing the products onto the conveyor. The cycle time for this operation, including all mould and robot motion, is of nineteen seconds. The problem boundary, based on the transparent box approach, is shown in Figure 2.

### 2.4 Product Design Specification and Quality Function Deployment

A product design specification (PDS) for the end effector was drawn up, outlining the customer’s requirements in terms of demands and wishes. With regard to the working environment, a demand was that the end effectors or robot plates needed to be able to work in proximity to hot mould tools. To satisfy performance requirements, the device needed to perform the basic part transfer operation; maintain the existing level of positioning accuracy; not damage the parts; be adequate for future products from the same part family; be able to handle hot, freshly moulded parts; and be easy to set up or reconfigure. The device needed to have a service life that would allow it to process one entire batch (approximately 50,000 units) as an absolute minimum. The device also had to be compatible with the existing bulk machinery. With regard to kinematics, the device would have to withstand high accelerations. The device weight was limited to a maximum of 5 kg, and size to 250 mm, due to robot payload and mould gap constraints.
During the disposal phase, the device needed to not harm the environment. To satisfy materials requirements, the device had to not affect the facilities and products; it had to be lightweight; it had to resist warping and deformation; and it had to be safe for workers to handle.

The design wishes included an ability to handle as large a number of batches as possible within its lifetime, and to have consistent performance characteristics throughout its life; to be inexpensive to develop and to have low running costs; to make use of readily available forms of energy; to be small and easy to store when not in use; to be easy and inexpensive to maintain; to be able to be fully or partially re-usable at the end of life; and to be made of readily available materials.

A quality function deployment (QFD) chart was drawn up to relate the company’s requirements and preferences to specific technical parameters. This is shown in Figure 3.

3. CONCEPT GENERATION

A morphological chart of candidate subsystems that would perform each of the required functions of the device was drawn up. A number of alternative concepts were generated for each element in the morphological chart. The concepts that were generated for the working principle are shown in Figure 4.

In the concept shown in Figure 4(a), the matrix of pins conforms to the object to be grasped, and the extended pins are then compressed against the object by a surrounding inflatable bladder. The concept of Figure 4(b) consists of a matrix of suction grippers, which would be used in conjunction with a customized blanking plate. In both these concepts the runners are disposed of in a separate process. In Figure 4(c), the conceptual solution consists of a flexible, soft polymer pad with perforations that can be connected to a vacuum pump. Runner removal can be performed using a high powered air jet. The concept of Figure 4(d) consists of a reconfigurable plug board to which suction and jaw grippers can be attached as required for each mould. In Figure 4(e), the conceptual solution consists of individual suction and jaw grippers that can be inserted in various positions along horizontal rails. The rails themselves can be attached to cross-rails for further position setting.

4. CONCEPT EVALUATION AND SELECTION

Concept evaluation was carried out using two design tools, namely failure mode and effect analysis (FMEA) in order to reveal potential failures of each conceptual solution, and a decision matrix to compare different solutions.

The first step in constructing a decision matrix was the establishment of the evaluation criteria. These were mainly based on the requirements specified in the Product Design Specification list and also on the constraints around the developed product. The criteria included several technical, economic and also safety factors, thus giving a broad spectrum of criteria on which the concepts could be evaluated. The factors chosen were those which are decision-relevant, as well as general constraints. The factors are also relatively independent of one another.
Not all the evaluation criteria have the same importance to the overall goal, since some criteria contribute more to the overall satisfaction of the customer requirements than others. The relative importance of each of the criteria is shown by the value of a weighting factor associated with each particular criterion. A weighting scale from 1 to 10 was used, 10 being the most important, and 1 being the least. The weighting values were determined from detailed discussions with the customer. Criteria which were given a weighting value of 10 were considered to be indispensable, and thus if a concept failed to satisfy these criteria, the concept in question was not considered an adequate solution to the overall project problem. The computed decision matrix is given in Table 1. The highest score in this exercise was obtained by Concept 5, the reconfigurable rails concept.

The FMEA exercise for the reconfigurable rails concept showed that the most likely potential failure modes of this concept could be countered with simple maintenance routines and good overall design. This concept was therefore selected for further development.

5. EMBODIMENT DESIGN, FABRICATION AND TESTING

After the solution concept had been selected, a new morphological chart was drawn up to evaluate and select the best methods to achieve the required functions of the prototype. Two key parameters that were analyzed were the locking mechanism between the grippers and the mounting rails, and the sliding mechanism between the mounting rails and the cross rails.

For the locking rail mechanism, the generated concepts included magnetic locks, screw friction locks, bolt locks, and spring loaded pin in hole locks. These candidate solutions were evaluated in terms of flexibility, set-up time, positional stability, cost, and availability. The selected concept for this function was the spring loaded pin in hole lock.
lock, due to its high position stability, and low cost and set-up time. A CAD drawing of the gripper fixture design is shown in Figure 5(a). A similar mechanism was selected for the movement and locking of the mounting rails relative to the cross rails, and a CAD drawing of the fully assembled system is shown in Figure 5(b).

![Figure 5: (a) gripper fixture design, (b) reconfigurable rail design](image)

After the detailed designs of the reconfigurable gripper were completed, a prototype was fabricated in order to test the reconfiguration and locking abilities of the system. For the prototype, the rails were fabricated out of mild steel box section, and the gripper fixtures were fabricated out of aluminium. Details of the prototype can be seen in Figure 6.

![Figure 6: (a) gripper fixture, (b) and (c) reconfigurable rail](image)

All of the sliding and locking functions of the prototype have been tested, and have been found to function well under the expected loads. During testing to failure, failure of the locking mechanisms occurred at between 6 and 8 kg loading. This load is well above the maximum weight of the parts to be handled, and exceeds also the payload capacity of the robots (see sections 2.2 and 2.4). Testing on the production equipment is scheduled to commence shortly.

6. DISCUSSION

This work has addressed two important issues in industrial automation, as discussed briefly in this section. The first issue relates to the critical decision that often needs to be made between flexibility and reconfigurability in manufacturing automation. In the current application, if a flexible solution had been selected, the gripper may have been able to handle the different sets of parts from all 400 moulds without human intervention between batches. The key question here however, is whether the greatly increased complexity and cost of such a gripping device would be justified in an application where large batches of approximately 50,000 identical units are being processed. The answer to this question, in our opinion, is negative. By selecting instead a reconfigurable solution, it is seen that, due to the large batch size, the added penalty incurred in reconfiguration time is in fact negligible when compared to the production time for each batch, and is well offset by gains in simplicity, reliability and lower cost.
The second issue relates to the fairly common problem, particularly in the plastics industry, of needing to grasp different sets of different objects in batch-wise fashion from the same working area. In this application, each set of objects corresponds to a particular mould, and in each set there are two types of objects to be grasped – the products and the runners – requiring two very different types of grippers. We have addressed this problem using two of the basic concepts of reconfigurability – modularity and adjustability. Through modularity, we are able to attach different types of grippers (in this case, suction-type and jaw-type) as required, and through adjustability we are able to place these grippers at the required locations. It is further noted that a key issue in modularity is the design of an appropriate interface between modules, and in our work this was achieved through the development of an appropriate setting and locking mechanism for the gripper fixtures to the rails. The required adjustability was achieved through the use of the sliding rails concept.

In the case study addressed in this work, the company is expected to achieve significant savings in costs related to the introduction of new products, since it will no longer need to develop new robot plates. The company is also expected to achieve significant reduction in the storage space need to store the handling equipment when not in use.

7. Conclusion

In this work, the design and prototyping of a reconfigurable end effector for the plastics industry has been presented. The developed concept has applications where different batches of products need to be unloaded from plastic injection-moulding machines during production, and where the number and location of products may differ between moulds. The end effector or so-called runners and sprues associated with the moulding process. A formal design approach has been adopted in the development of the solution, and this has led to a solution, from several alternatives, that best satisfies the various requirements of the customer. The developed solution may have further applications in automation outside of the plastics industry, in situations where a number of objects need to be grasped simultaneously using different types of grippers, in an environment of high variety between batches.

ABSTRACT

In small, geographically isolated economies, it is possible to find a lack of appropriate support for the implementation of state-of-the-art technologies and methodologies for manufacturing automation, thus compromising the efficiency and competitiveness of the manufacturing sector in the global marketplace. In this work, we carry out a critical investigation of the use of automation within the manufacturing sector of such an economy, using the island nation of Malta as a case study. We focus mainly on high value-added manufacturing, characterized by the need for high product variety and relatively low product quantities, and triggering the need for versatility in production facilities, potentially in the form of reconfigurable production systems. We have developed a set of detailed questions, in the form of a survey questionnaire, which we pose to a sample of companies from various sub-sectors, and of various sizes, within the Maltese manufacturing sector. Respondents answer the questions in the setting of a semi-structured interview, following an extensive familiarization tour of the company facilities by the interviewers. We present the results, as well as their analysis and interpretation, from our first sample of thirty manufacturing firms, ranging in size from micro to large, and taken mainly from the electronics, medical, pharmaceuticals, plastics, food and beverage, chemicals, and furniture industries.

1. INTRODUCTION

In the past decade, various authors have discussed the emerging challenges related to the continuous struggle faced by manufacturing companies to improve efficiency and effectiveness [1]-[5]. These challenges affect different manufacturing sectors to varying extents, however in general they continue to become more stringent, for a number of reasons. Firstly, customers are expecting a much larger amount of product variety and increased quality. Secondly, as time passes, there is continuous progress in technology, and as a result, products are constantly evolving so as to incorporate new technologies. Manufacturing systems and processes are also being affected with this advancement of technology due to the development of new techniques, processes and equipment. The introduction of regulations is already having an effect on the manufacturing industry, both due to regulations affecting the product, as well due to regulations affecting the production of products or the processes. Another existing challenge concerns the shift to an ever-expanding globalised market, with manufacturing companies no longer having to compete only against local companies, but nowadays having to compete against distant and/or foreign companies as well.

However, such studies have generally been based on relatively large countries and economies, or else been based on very general overall situations. The specific aim of our work is to carry out a critical investigation of the manufacturing situation within a small and geographically isolated economy, with a focus on the implementation of industrial automation, and to identify and address problems that exist. So solutions to identified problems will be developed with a focus on the reconfigurable manufacturing systems paradigm. This paradigm was developed in the early 1990s and early 21st century, and various authors have discussed Reconfigurable Manufacturing Systems (RMSs) [2], [3], [5], Reconfigurable Equipment [6], and Reconfigurable Machine Tools [7]-[9]. Such systems bridge the gap between Dedicated Manufacturing Systems and Flexible Manufacturing Systems, and combine the advantages of both approaches. RMSs are built around a part family, or part families, allowing product variants within the respective part family/families to be manufactured through a

rapid and relatively simple reconfiguration of the equipment. Reconfigurable equipment has the potential of substituting, exchanging, adding, removing, and/or modifying specific modules to change a new existing RMS configuration into a new configuration with different capabilities.

This paper focuses on the first part of our overall project. The primary targets of this specific study are to investigate the perceptions and problems relating to manufacturing, with a focus on automation, that are experienced specifically by companies operating within a small and geographically isolated economy. As a case study, the current situation in the Maltese Islands has been taken.

Malta is an island nation, and European Union (EU) member state, in the middle of the Mediterranean Sea. It has a population of 400,000 and a gross domestic product (GDP) of about €5.7 billion ($7.4 billion) [10]. The manufacturing sector accounts for about one fifth of the GDP. The Maltese economy has experienced a transition in the last decade whereby the traditional low technology mainstream manufacturing sector experienced difficulties due to its heavy reliance on manual labour. Therefore, Malta’s focus has been directed towards high value-added manufacturing, in an attempt to enable industry to achieve productivity growth to engender prosperity and wealth. Analysis has shown that the European manufacturing industry consists in large majority of SMEs (Small and Medium Enterprises), with over 99% of companies and 58% of manufacturing employment falling within this group. In fact, these SMEs generate the majority of new and innovative products, providing some three-quarters of EU exports. Malta’s economy as in the case of other EU countries is characterized by a predominance of SMEs. These businesses are not only fundamental to the on-going economic activity, but are also a complementing arm of industry in general since these would supply the larger companies making up the industry.

This study therefore has two objectives with respect to the Maltese manufacturing sector: an information gathering objective, and a problem identification objective, with the particular focus being automation in high value-added product manufacturing. The results of this study, although specific to the Maltese manufacturing environment, may also be widely relevant to other pocket economies within the EU, as well as within the rest of the industrialized world.

2. PRELIMINARY GUIDELINES

To thoroughly achieve these two primary objectives of this study it is required to carry out an extensive investigation of the local scenario through the gathering of information about various issues relating to manufacturing and industrial automation. The companies that have been investigated so far have been chosen at random from an exhaustive list of manufacturing companies compiled from databases taken from various sources.

The companies within this list were categorized according to the nature of the products produced within each company, e.g., medical, pharmaceutical, furniture, chemical, etc. Twenty-one manufacturing sub-sectors were outlined. These sub-sectors were put in a priority list as outlined in Table 1 in terms of the nature of the products manufactured. Perceived high-volume discrete product manufacture and consumer product manufacture were given a high priority (in this case level 1 and level 2), whilst products that tend to be one-offs, such as infrastructure, and high-volume production of the same product, such as paper manufacture, were given lower priorities (in this case level 3 and level 4). This study aims to investigate the high priority manufacturing sectors.

Apart from the manufacturing sector within which a particular company operates, another important factor that may lead to characteristic problems is the actual size of the company in terms of the total number of employees. Each category has thus been further subdivided into four sub-categories according to the number of employees within each manufacturing company, namely: micro-sized companies, having less than 10 employees and with a turnover less than €2 million; small-sized companies, having less than 50 employees and with a turnover less than
€10 million; medium-sized companies, having less than 250 employees and with a turnover less than €50 million; and large companies, having more than 250 employees, as per the definitions in [11].

3. SURVEY DEVELOPMENT

3.1 SURVEY FORMULATION

As mentioned in the previous section, this study has two main objectives; a critical investigation, and a problem identification objective. The gathering of information is mainly through a detailed survey, consisting of two main sections. The first section contains general questions relating to the company and the manufacturing approaches and means implemented. This first section is intended to be answered by all respondents. The second section focuses on automated manufacturing, and is therefore intended for respondents that already implement automated machinery.

The first section of the survey starts off with general questions related to the company being investigated, such as a description of the manufactured products, company size, as well as the number of employees. As mentioned above, certain characteristics may arise that can be correlated to each of these separate factors. Therefore, such questions were required to position the company in the right categories, mainly with respect to sector and size, so as to be able to analyse trends of these separate categories.

As indicated above product lifetimes are constantly decreasing, that is the time between the initial stages of production to the time when the product is not manufactured any more. This being a very important driver for the subsequent manufacturing approach implemented within a company, there was a need for a question related to the lifetime of the products being produced by the company being interviewed.

The next questions tackle specifically the manufacturing approach and processes currently being made use of within the production facility of the company being interviewed. In this specific study, the broad categorisation of manufacturing approaches has been taken to be manual, semi-automated and fully automated. Manual processes are processes made up of mostly manual labour. A semi-automated manufacturing approach refers to operations being split between manual and automated, whilst fully automated processes refer to processes run fully autonomously or with minimal human intervention. Respondents could choose any of these approaches; or multiple approaches if different approaches are undertaken for different manufacturing processes. The reasons given by the respondents for their choice of manufacturing approaches were also requested. Some potential reasons that were identified beforehand, and given to the respondents to choose from, include product variety, production volumes, and product/process complexity. In addition, respondents were also questioned about specific production processes implemented on their shop-floors, and whether such processes are fully manual, semi-automated or fully automated.

In order to determine the use, or the lack of use, of automation equipment, it was considered necessary to inquire about any perceived problems towards the implementation of automation equipment and industrial stand-alone robot arms. To gather with this information, other questions that tackle issues relating to the willingness to invest in automation in relation to customer pressure and/or to competitor facilities were also included in the survey.

The second section of the survey is more focused on automation and its implementation, and as mentioned, is reserved only for respondents that currently already employ some level of automation. The first question in this section relates to the identification of equipment that generally is implemented for automated manufacturing. Respondents are given a list of such automated equipment from which they have to tick any already implemented equipment. The list includes Computer Aided Design (CAD), dedicated automation equipment, specialised automation equipment, Computer Numerically Controlled (CNC) machining equipment, pneumatic/hydraulic devices, flexible or reconfigurable automation, and machine vision. This is required so as to determine what facilities are currently being used the most in automation. In addition, it was deemed useful to understand where the design and manufacture of such automation equipment is undertaken. Common approaches include companies designing and manufacturing their equipment in-house, with others subcontracting it to local as well as foreign mainland equipment manufacturers. In the case of certain subsidiary companies, the technology, processes, and even any required equipment may be directly adopted from the respective mother/sister companies. As a result, all these options were included from beforehand in the survey. For each option chosen, the respondents were also required to give the reasons for their choice. Some possible reasons that were included from beforehand in the survey include quality and available expertise; however respondents were encouraged to add to the list.
The next set of questions, relate to how the companies react with respect to the implementation of automation equipment when a completely new product is to be introduced to the existent product portfolio. This would be useful to determine whether a new system would be opted for straightaway or whether the existent system would be considered for the manufacturing of the new product thus resulting in reconfigurability of the automation equipment.

Besides reconfigurability of automation equipment, this study is also interested in flexible automation and whether this specific philosophy of manufacturing is actually implemented or not. A number of questions were introduced in order to determine whether equipment with extra in-built capabilities would be considered even though at that point in time, there would be no use for all its capabilities. Also, it was deemed useful to determine whether if this is opted for, the equipment would actually later be used to its full potential or not.

The next questions address the utilization of specific equipment for various different products, with a focus on reconfigurability and modularity. First, the issue of whether the current production equipment is to a particular extent modular or not was tackled. Following this, respondents were asked whether the equipment utilized for the manufacturing of a particular product is re-used or reconfigured when the lifetime of the respective product reaches an end. Subsequently, the frequency of “engineering changes” on an existing production system was requested, with the term “engineering changes” being used in his particular study referring only to changes that require a certain degree of new engineering input, and hence not including work order changes. This was followed by the reasons causing these changes, and a list was a gain made available to the respondents. The list included regulations and/or customer requests, quality requirements, capacity requirements among others. Finally, the typical extent of changes and the time taken to carry out the changes were asked. These questions would be required to determine the degree of changes and thus the requirement to adapt quickly to new set-ups.

The final question of the survey focuses on the relationship between product design and product manufacture, focusing on the extent to which the product design may be affected by the manufacturing set-up itself. Product design is one of the initial stages of the product life time, with manufacturing following at a later stage. This question would give an indication on how the product design may affect the modularity or reconfigurability of the production facilities used and the extent to which the product design may be affected in order to automate the process on which the product will be manufactured.

### 3.2 Survey Implementation

Following a number of test runs, it was decided that the methodology adopted for the gathering of information through the survey would consist of conducting a semi-structured interview with an appropriate company representative(s). This company representative(s) ideally had to be very familiar with the production activities within the company, such as the head of manufacturing department or operations manager. The semi-structured interview included a physical tour within the manufacturing facility of the company and subsequently a discussion on the survey questions. The discussion as well as the tour proved to be a valuable source of information towards the completion of the survey questions. In fact, this was confirmed during the test runs that were conducted. Even though lengthy, this methodology improved consistency in the answers given by different respondents due to the fact that, the replies to the questions asked were always recorded by the same person. To date, thirty interviews have been conducted from the sub-sectors with priority weighting 1 and 2. The breakdown of the companies interviewed by sector and size can be seen in table 2.
4. PRELIMINARY RESULTS

This section discusses the results obtained from the preliminary analysis of the first sample of thirty surveys performed. However, it is pointed out that this analysis is still a general one due to the relatively small number of surveys performed within each sub-sector. The trends within each particular sub-sector and size category require more surveys to be performed.

4.1. PRODUCT LIFETIME

It was interesting to note that approximately half of the companies answered that their product has a lifetime of more than 5 years as illustrated in Figure 1. Another twenty percent produce products with a lifetime between two and five years. The rest of the respondents have products with lifetime of up to 24 months. Thus a trend can already be seen, with the majority of cases being companies having quite lengthy product lifetimes, which contrasts with some descriptions of current trends found in literature. Through various discussions with manufacturing personnel from such companies, a common reason for this behaviour was that the companies are subsidiaries having foreign mother companies, with the trend being that the mother companies move those products that have already reached their maturity stage to the plant in the small country. Newer products are possibly manufactured nearer to the customers, since they would still be under development. Since products that have already reached their maturity stage, in general, tend to start decreasing in volume, the companies in the small countries would end up producing an increasing variety of batches/types of products, with each of these having a relatively small volume. This would result in having a good number of products with relatively low volumes to be produced for a considerable length of time.

![Figure 1 - Product lifetimes against percentage number of respondents](image)

4.2. MANUFACTURING PROCESSES

Having a large variety but low volume products portfolio was given as one of the main reasons why fully manual manufacturing processes are still adopted by many of the respondents, totaling forty percent of the survey respondents. These respondents commented that the utilization of manual processes is due to requiring various changeovers in the production setup, and therefore necessitating a high degree of flexibility in their processes so as to be able to quickly adapt the process to all the product variations required. However, another primary reason for the adoption of manual labour is the complexity of mechanical assembly, with the most common manual processes being material transfer, packaging, and inspection.

Semi-automated processes were implemented when the requirements of quality and efficiency were deemed to be the primary manufacturing issues. In fact, this was the case in forty percent of the interviewed companies. In such cases, any mechanized processes such as injection moulding are also included. Other techniques include printing and cleaning processes. The semi-automated processes are also characterized by higher volumes. However, it is important to note that the responses noted that their clients do not generally impose the requirement of automating the processes.

Fully automated processes are only employed by about one fifth of the interviewed companies. The reason given for implementing fully automated processes is mainly due to high production volumes. The most common fully
automated manufacturing processes include soldering processes, especially in the electronics industry, as well as printing processes.

4.3. IMPLEMENTATION OF AUTOMATED EQUIPMENT

With the implementation of automation being relatively limited, it is important to investigate whether there are some perceived problems for the implementation of automation. A common and significant problem that has been encountered in practically all companies is the lack of time to study opportunities. A reason for this may be that in small and geographically isolated countries, most often all companies are relatively small. Even companies that are regarded locally to be large, in fact are still relatively small when compared to mainland companies. This results in these smaller companies having to compete with larger competitors while seeing everyday routine non-manufacturing tasks as well, such as maintenance works. These everyday non-manufacturing tasks would make it difficult for them to study opportunities to enhance their productivity. In addition, the exposure to newly developed technologies through relevant industrial shows, exhibitions, and fairs is minimal, due to the relative isolation of the economy.

Besides the above discussed reasons, there are other perceptions that hinder the use of automation equipment. Continuing from the lack of exposure to manufacturing technologies, these include the perception that such equipment is not appropriate for the products or for the volumes being produced. This is especially identified when automation equipment such as stand-alone industrial robots were discussed. Another high rating perception is that the equipment and its relevant required implementation are too expensive. Such respondents argue that it all depends on the volumes being produced. With the already identified low production volumes, such investments are regarded as not being justifiable.

4.4. DESIGN AND MANUFACTURE OF MANUFACTURING AUTOMATION EQUIPMENT

When automation equipment is actually implemented, the most common approaches include making use of dedicated and specialized automation equipment, flexible and reconfigurable equipment, as well as machine vision. The common approach is for the design of such equipment to be outsourced to specialized manufacturers outside of the country; however modifications and adaptations are usually done in-house. This is due to the fact that for such complex manufacturing equipment the knowledge of complex processes and technologies is considered to be in the hands of developers who are specialized within that particular manufacturing field, and thus are readily equipped with the knowledge and technologies required. Therefore, local manufacturers outsource this equipment with the perception of obtaining high quality equipment. The manufacturing of such equipment is also mostly left in the hands of these foreign based industrial equipment manufacturers. However, when it comes to the development of relatively simple equipment or a slight modification to equipment, the common approach is to outsource such tasks to local manufacturers or else they are performed in-house, with both these approaches opted for due to financial reasons.

4.5. NATURE OF THE PRODUCTS AND INDUSTRIAL MANUFACTURING EQUIPMENT

It was observed that many of the investigated companies specialize in the production of part families, with the products that they manufacture being to a certain extent similar to each other in nature. In fact, in most cases, even new products that would be added to the current product portfolio would also be similar in nature to those already existing or to past products. Therefore, it would be possible to include them in already existing setups without major changes. In fact, when discussing this issue, most of the survey respondents said that when new products are to be introduced, these are in fact added on to the already existing production lines. In fact, when investing in industrial manufacturing equipment, the common approach is to invest in equipment having extra in-built capabilities. The approach taken is to utilize this equipment to manufacture the product portfolio, which is as broad as possible mentioned, within each manufacturing company. These considerations can be regarded to be a broad product family. Still, respondents pointed out that many times, the extra in-built capabilities invested in when buying the equipment are still not all made use of. When it comes to the end-of-life of a current product, these trends are reflected on the approaches taken with regards the manufacturing equipment that was already utilized for that particular product. This is illustrated in Figure 2, which illustrates the most common actions taken for the manufacturing equipment for new products.

4.6. CHANGES TO EQUIPMENT

It has already been established that the lifetime of the products manufactured by the companies interviewed, is, in general, relatively long. This is together with the fact that the products would be past their development stage, would mean that no alterations of “engineering changes” would be required in the processing facilities. In fact as opposed to work order changes which occur on a daily basis due to the various different products manufactured, the
survey showed that such engineering changes occur very rarely, with these changes occurring every few years. The main reasons for these changes when they occur include requirements for quality improvements, new implemented regulations, new products adaptation, as well as capacity changes that are beyond what was catered for initially. The typical extents of these changes are minimal hardware and/or software changes; with the time to carry out such changes ranging from only a few hours to a few weeks.

4.7. PRODUCT DESIGN

Another interesting point that arose from this study is that no product design activities are present in most of the investigated companies, with the main reason being that the majority of respondents are subsidiaries to larger companies. In these cases the trend is that the mother company develops the product design, with this design being handed over to the local companies. These local subsidiaries would therefore have to manufacture the already designed products. As was discussed in a previous section, these products tend to also have already reached their maturity stage, and therefore would be well past their developmental process. This further limits any possible changes to the product design.

5. DISCUSSION

Many of the key characteristics of manufacturing companies that were identified in this study, with regards to manufacturing and industrial automation equipment, may be relevant to other small and/or geographically isolated economies. One of the key points is that most of the thirty companies investigated have a product portfolio composed of broad product families, each of these having a large amount of products which despite having differences amongst themselves, can still be categorized and grouped together due to a high percentage of similarities. During the investigation, this was mostly encountered in micro-sized companies. The end result would be that such companies opt for fully manual manufacturing processes with the perceptions that there is no other feasible way. The lack of industrial fairs and locally based industrial equipment manufacturers continue to reinforce this perception. It is clear that manufacturing companies operating within such a pocket economy can not stay competitive for long without the exposure to new and improved manufacturing approaches, ways, and means. The survey has revealed that companies that do attend industrial fairs tend to be much more open to innovative and advanced manufacturing methods. This implies that such exposure may be of great importance to local companies, to enable them to be competitive with mainland companies, which in today’s globalised markets have become direct competitors.

It was also noted that in companies where the products have been around for a significant amount of time (several years), such companies are less willing to take up new products and try to achieve a larger market share. This is especially the case for subsdiary companies. In such cases, it is not unusual for the mother company to decide and impose the products that the company in question should manufacture, with these products potentially even being those that the mother company deems not worth marketing anymore, but is forced to continue producing for example for past use rs. Therefore, the common approach is for no investment to be considered in such
production lines. Further to this, some local companies were identified to be less willing to invest in new manufacturing approaches, with the mentality of “if we have managed during the past decade, we will manage during the coming decade as well”. Such a mentality exists especially in those companies that have very limited exposure to new and innovative ideas from outside the company.

During the discussions with manufacturing personnel, other factors not directly mentioned in the survey were also brought up. In more than one instance it appeared that the potential enlargement of the physical factory size was an issue. Companies seem to find it difficult to enlarge the physical size of the factories, with the main reason being attributed to the documentation and bureaucracy necessary for such a move. Another recurring issue in these discussions with several manufacturing organisations relates to the lack of networking between the local factories themselves especially in the case of micro and small companies. This is unfortunate for multiple reasons, including the consequent absence of sharing of potential solutions and of the identification of possible customers through subcontracting. Lack of networking also affects the already existing local automation service providers. Due to this lack of communication and networking, many of these service providers are still relatively obscure, with only a few being known by the majority of companies.

In concluding this preliminary investigation of the data obtained from the survey, one can note that for a survey of this nature, it is essential that a company tour be taken prior to the actual interview. The survey itself is at times too general and thus not capable of capturing all the information that is being obtained through the tour and the discussions being taken up with the respondent.

6. CONCLUSION AND FUTURE WORK

Further surveys will be performed with more companies from the various outlined manufacturing sub-sectors. This will give the possibility to analyse the various sub-sectors, together with the company size categories, on their own. Following this, the perceptions and problems related to manufacturing currently existing within particular sub-sectors could be determined. After an-depth analysis of the identified manufacturing perceptions and problems, the project will then proceed to address these specific manufacturing issues that emerge from this study.

ACKNOWLEDGEMENTS

This work is funded under the Maltese National Research and Innovation Programme through the Malta Council for Science and Technology. The research team would also like to thank all those companies that have till now participated in this study.

ABSTRACT

Various fault detection methods based on statistical concepts such as non-stationary SPC chart, PCA, PLS, Hotelling’s T2 are widely used in order to detect the fault of the cyclic signal. In practice, even for the identical processes, however, the physical time lengths of cycles differ, and often signals are not available from some designated sampling points for various reasons, these are missing data. Therefore those classical methods are not suitable for real world process data which has different sampling lengths even missing values.

In this paper, a new fault detection method for stepwise cyclic signal using spline regression and support vector machine (SVM) is proposed. Regarding step changing point of data as knot point, a cyclic signal is regressed on the spline function. After then, features are extracted from the regressed spline function as the value of coefficients which is multiplied by each basis functions. With these features, it becomes much easier to attribute the reason of fault to actual trouble step. By using those features from the normal and faulty sets, SVM classifiers are constructed. Those constructed SVM classifiers are not just able to detect the relation between the normal and the fault but also able to classify between the faults. Furthermore, by using fault data as well as normal data, SVM classifier is expected to asymptote to optimal classifier. Performance evaluation of the proposed methodology is provided.

1. INTRODUCTION

Industrial revolution has greatly influenced on the fields of manufacturing. It enables mass production by using manufacturing machineries; changes the main cause of quality. Quality, which was effected by experiences of workers, nowadays, depends on the status of production equipment [1]. To improve quality, various methods to measure the manufacturing devices have been developed. Among them, Shewhart control chart, proposed by Walter A. Shewhart of Bell Laboratory in 1920s, is the most widely used and well developed method in theory [2].

As technology becomes more complex, manufacturing processes need more delicate method to control. Recently lots of manufacturing processes require, in general, controlling dynamically varying abundant variables under a closed-loop. Moreover, developments of manufacturing technology and information technology make it possible to use real-time data that reflects the status of manufacturing processes. Consequently, the concept of process control is changing to controlling non-stationary variables rather than keeping the stationary attribute value. Hence, it is important to have a process controller designed to maintain satisfactory operations by compensating for the effects of disturbance and changes occurring in the process [3].

Even though, there exist variations unable to be controlled by process controller. Fault is defined as a change, of parameters or characteristic properties which reflect the status of processes, which cannot be handled by controller [3]. If any variable exceeds the limit of acceptance, that situation can be regarded as a fault. By applying that philosophy, the statistically computed acceptance could be set as a criterion for detecting faults. Those procedures are called fault detection, determination of the faults present in a system and the time of detection [4].

To conduct fault detection for non-stationary signal, analysis methods have been proposed regarding a sampled point over given time horizon as a variable. Non-stationary SPC chart, which sets up the upper control limit (UCL) and lower control limit (LCL) by computed mean and variance of each time-point variable, is very popular method for detecting faults. Applying CUSUM chart [5] or EWMA chart [6] to time-point variables, in addition, has been proposed which enable to analyze in view of time series [3]. In case that signals have large length, then the number of chart for variables to control increases. Moreover, those control charts do not consider the inter-effects between the variables. Multivariate statistical analysis methods, such as Hotelling’s T2 chart, principal component analysis (PCA)

Flexible Automation and Intelligent Manufacturing, FAIM2009, Teesside, UK

partial least squares (PLS), are adopted for this reason [7]. To enhance the ability of analyzing effects caused by time, researches on fault detection method using wavelet have been conducted [8, 9].

These methods have difficulties to deal with the real-world data. Cyclic signal, generated from general processes, is a sequence of steps which have common characteristics. Even for the identical processes, the physical time lengths of cycles differ as shown in figure 1. At the point of step-changing, due to high variances of signals, probability to commit type II error increases. Often signals are not available from some designated sampling points for various reasons, what are called missing data. In this case, estimating the status of the time has difficulties when sampled data are missing. Fault detection method to deal with real-world data needs pre-processing algorithm to adjust the physical length of signals so that each signal has same length.

![Figure 1: Heterogeneous lengths of steps [10]](image1)

However, there exist tendencies to lose the characteristics of signal and to magnify the effect of unexpected noise when pre-processing algorithms are applied. Figure 2 and 3 show factors that affect the value of sampled signal. In figure 2, \( f(x) \) means designated pattern of signal by a process engineer. Contrary to the engineer’s hope, it is natural that white noises \( \epsilon \) are added to the designed pattern. Process system, in accordance with a recipe originated by the process engineer, follows a pattern of \( f(x) \) combined with \( \epsilon \).

![Figure 2: Nature of signals – in continuous field [10]](image2)
A Research on Fault Detection and Classification of Cyclic Signals Using Spline Regression and Support Vector Machine

Figure 3: Nature of signals – in discrete field [10]

It is impossible to know what are happening in continuous fields. Data we have are signals sampled at a specified interval of time. Furthermore, measurement errors that occur in sensor devices, $e_t$, are also added. Signal sampled at time $t$, $s_t$, can be expressed as the summation form of these factors $s_t = f(x_t) + e_t + e_t$. Thus, ultimate objective of fault detection is examining the variations in continuous fields rather than that of gathered signals [10].

In this research, feature extraction method using spline regression is proposed which prevents trends of losing characteristics of signals and magnifying undesirable noise. Following to [10], a problem exists in scale. In this time, features are divided by its variability calculated as standard deviation. By doing this, features are stabilized. Fault detection algorithm conducted by support vector machine classifier is introduced in [10] constructed on the features extracted by proposed method. In addition, support vector machine fault classification method will be discussed. Benchmark test is given to analyze its performance and remarkableness in comparison with conventional method.

2. **SPLINE FEATURE EXTRACTION**

Spline is a function defined piecewise by polynomials on partitioned domain. In this case, by focusing on the univariate polynomial spline, spine function $S(\cdot)$ defined on $[a, b]$ maps them to $\mathbb{R}$, the set of real numbers. $S(\cdot)$ is composed of real-valued piecewise continuous functions $P_i(\cdot)$ defined on a subinterval $[t_i, t_{i+1})$. That is,

$$ S: [a, b] \rightarrow \mathbb{R} $$
$$ P_i: [t_i, t_{i+1}) \rightarrow \mathbb{R} $$

such that $a = t_0 < t_1 < \cdots < t_{k-2} < t_{k-1} = b$ and

$$ S(t) = \begin{cases} 
    P_0(t), & t_0 \leq t < t_1 \\
    P_i(t), & t_i \leq t < t_{i+1} \\
    \vdots \\
    P_{k-2}(t), & t_{k-2} \leq t < t_{k-1}.
\end{cases} $$

The given $k$ points $t_i$ are called knots [11]. Spline functions are classified, based on the way it is defined, into cubic spline, natural spline, smoothing spline and so forth.

General method to represent a form of spline is linear basis expansion. For a $p$ dimensional vector $x$, transformation function $h_m(x)$ is defined on $\mathbb{R}^p$ maps them to $\mathbb{R}$. By linear basis expansion, $f(x)$ can be represented as linear combination of transformation function as shown in (3).
Flexible Automation and Intelligent Manufacturing, FAIM2009, Teesside, UK

\[ f(x) = \sum_{m=1}^{M} \beta_m h_m(x). \] (3)

\( h_m(x) \) called a basis of function \( f(x) \). Linear method can be easily adopted if every \( x \) in the domain is transformed through basis function. So that, the parameters \( \beta_m \), which shape the function, can be simply calculated. By generating basis functions determined by the type of spline and estimating the parameters \( \beta_m \) with linear techniques, spline function \( S(x) \) is acquired [12]. From now on, regard \( x \) as univariate variable which denotes sampling time of a signal; focus on cubic spline.

When cubic spline function has 2 knots, \( \xi_1 \) and \( \xi_2 \), the basis of the function can be defined:

\[
\begin{align*}
h_1(x) &= 1 & h_2(x) &= x \\
h_3(x) &= x^2 & h_4(x) &= x^3 \\
h_5(x) &= (x - \xi_1)^3, \\
h_6(x) &= (x - \xi_2)^3
\end{align*}
\] (4)

where \( \eta \) is a function that has a value \( x \) when \( x \) is greater than 0; 0 otherwise. This definition implies that \( h_5 \) and \( h_6 \) have meaningful information only when \( x \) is greater than \( \xi_1 \) and \( \xi_2 \) respectively. These characteristics are different from those of \( h_1, ..., h_4 \). So, we can regard the parameters \( \beta_1, ..., \beta_4 \) multiplied to \( h_1, ..., h_4 \) as features that reflect whole trends of a signal. In a different way, \( \beta_5 \) and \( \beta_6 \) multiplied to \( h_5 \) and \( h_6 \), which have meaning only on fixed region, can be considered as feature of specified regions. Also cubic spline function is second-order differentiable, \( \beta_5 \) and \( \beta_6 \) are able to be interpreted as evaluations of variation between the subintervals.

With these characteristics of spline, feature extraction for cyclic signals composed of some steps can be done efficiently. Data of cyclic signals we have is \( s_i \) sampled signal at a point of time \( t \). By setting step changing point to knot point, sampled values are regressed on basis generated by cubic spline. If there are \( k \) steps, \( k+3 \) bases can be generated. Through the procedure, parameters \( \beta_1 \) to \( \beta_{k+3} \) multiplied to each basis are obtained; those \( k+3 \) values are treated as the features of cyclic signal \( s_i \).

Spline feature extraction capacititates to project cyclic signals, of which length are different, to same \( \mathbb{R} \) space, so that various statistical method can be easily applied. Since \( \beta_1, ..., \beta_{k+3} \) are the features that reflect the characteristics of a specified subinterval, it is possible to trace when faults occur. Unlike conventional fault detection methods, condition for homogeneous interval length and no missing points are not required by the reason that the method is based on regression which doesn’t require any strict conditions of missing data and same interval [10].

As stated in [10], however, these features are not in the same scale. Though the features well reflect the characteristic of each subinterval, the each variability of features is quietly different. So, these features need to be standardized. In this research, method to standardize via dividing by its standard variance is provided. Also, mean squared error of the signal is regarded as feature. Hence, a 5-stoped signal has 9 features.

3. Fault Detection and Classification Based on Support Vector Machine

Support vector machine is a method of supervised learning, which maximize geometric margin [13, 14]. Suppose a given set enables to supervise training; the set can be stated as (5).

\[ D = \{ (x_i, c_i) \mid x_i \in \mathbb{R}^p, c_i \in \{-1, +1\} \}_i \] (5)

\( x_i \), defined on \( p \)-dimensional space, is called input variable and \( c_i \) is called class label which corresponds to \( x_i \). Supervised learning is applicable due to class label \( c_i \) is known. Support vector machine classifier has a form of hyperplane \( w \cdot x - b = 0 \) which separates two classes. Geometric margin \( 2/\|w\| \), which represented in Figure 4, should be maximized. Without loss of generality, maximize \( 2/\|w\| \) problem can be reformulated as minimize \( \|w\|^2 \).
In order to construct support vector machine classifier for inseparable case, shown in Figure 4, slack variable $\xi_i$, which represents degree of misclassification is introduced. Penalty cost $C$ multiplied by the summation of all $\xi_i$ is added to objective function which minimizes the inverse of squared margin. From this, the optimization problem (6) can be formulated, that is,

$$\begin{align*}
\text{(P)} \quad \min & \quad \frac{1}{2} \|w\|^2 + C \sum_{i=1}^{n} \xi_i \\
\text{s.t.} & \quad c_i (w \cdot x_i - b) \geq 1 - \xi_i, \quad 1 \leq i \leq n
\end{align*}$$

and its dual program is obtained[12] as (7),

$$\begin{align*}
\text{(D)} \quad \max & \quad \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{n} \alpha_i \alpha_j c_i c_j (x_i^T x_j) \\
\text{s.t.} & \quad 0 \leq \alpha_i \leq C, \quad i = 1, \cdots, n \\
& \quad \sum_{i=1}^{n} \alpha_i c_i = 0.
\end{align*}$$

As a result of solving (7), support vector machine classifier can be defined as (8), where $\text{sgn}(x)$ is a function that returns $+1$ when $x$ is greater than 0; $-1$ otherwise.

$$f(x) = \text{sgn}(w^T x + b) = \text{sgn}\left(\sum_{i=1}^{n} c_i \alpha_i (x_i^T x) + b\right)$$

The greatest advantage of support vector machine, originally linear classifying method, however, is availability that can be transformed to nonlinear classifying method by using kernel trick. Only positive definiteness of kernel function is satisfied, support vector machine can be altered in numerous different shapes. For any positive definite kernel $K(x, y)$, dual problem and classifier can be formulated as (9).

$$\begin{align*}
\text{(D)} \quad \max & \quad \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{n} \alpha_i \alpha_j c_i c_j K(x_i, x_j) \\
\text{s.t.} & \quad 0 \leq \alpha_i \leq C, \quad i = 1, \cdots, n \\
& \quad \sum_{i=1}^{n} \alpha_i c_i = 0
\end{align*}$$

$$f(x) = \text{sgn}\left(\sum_{i=1}^{n} c_i \alpha_i K(x_i, x) + b\right)$$
By applying various kernel functions and adjusting its shape parameters, more accurate and asymptotic classification is feasible to be done.

In former research [10], extracted features through using spline regression are used as the set of support vector machine fault detection. Just data which is known as fault or normal exist, training set can be formed; support vector machine classifier is constructed. Continuing the former research, in this paper, method to classify the types of fault is presented. At first, fault detection is performed on the given query data. In case that the query data is decided as fault, classifiers constructed to divide the classes of fault are at work to determine the fault-class of the data. Suppose there are three classes of faults, fault-class A, B, C, three classifiers should exist to separate between A and B, B and C, C and A. By majority voting from the results of three classifications, fault-class of query data is obtained.

4. NUMERICAL EXPERIMENT

Using real data originated from semiconductor/display FAB process is most desirable to evaluate the performance of fault detection algorithm for the case that it applied to real case. Due to security policy, evaluation results of real data cannot be written in this paper. Accordingly, artificial data are used which resembles chiller temperature in photolithography process.

4.1. DESCRIPTION OF DATA

As shown in Table 1, a single signal is composed of 5 main steps. Each step has sampled length as represented in Table 1; its length can vary within the range of ±5%. During the main step, signal will follow the defined function. White noises, however, which follow normal distribution with mean 0 and standard deviation 3, are added to the whole process signal. Figure 4 shows the prototype of generated signal.

![Figure 4: A prototype of generated signal](image)

<td>High variation (std = 5) in step 3</td>
</tr>
<tr>
<td>type 3</td>
<td>Irregular step length (&gt;5) in step 4</td>
</tr>
</tbody>
</table>
Three types of faults are defined (Table 2). Type 1 faults are defined as occurrence of mean shift with amount of +4 in step 2. If a signal is classified as type 2 faults, that signal has high variance white noise in step 3. Finally, a signal is regarded as type 3 faults when lengths in step 4 are distinguishably long.

### 4.2. DESIGN OF EXPERIMENT

The sets of randomly generated signals are formed to evaluate the performance of methods. Three sets are generated. First set is composed of normal signals in the proportion of 70% and rest of signals follow type 1 fault. In the same proportion, set 2 and 3 are the mixture of normal signals and type 2-3 fault ones respectively. Each set consists of 100 signals.

Not only verification of fault detection sensitivity, but also validation for fault classification should be done. For total 200 signals, 70% of them are regarded as normal, rest of them are split into three types appeared in Table 2 with same ratio. The fault detection and classification are done for the generated set following to the methodology introduced in chapter 3.

For evaluating generated data sets, performance test was done. These results from the 5-folds cross validation test. In order to compare fault detection algorithms, total 7 methods are considered. Non-stationary chart is one of them. Following to convention, 3-sigma control limits are set up. However, tolerance limit for faulty point is fixed for the sake of coordinating tradeoff between type I error and type II error. For extracted features by cubic spline method, Hotelling’s \( T^2 \) method and support vector machine are considered. The probability of Hotelling’s \( T^2 \) defines the size of ellipsoid, is set as 0.5, 0.7 and 0.99 to modify its ability to detect faults. In the case of support vector machine, Gaussian kernel and inverse multi-quadratic kernel with are considered as the control part of this research.

### 4.3. RESULT

In those tables, 'alpha' stands for the probability of occurrence of type I error - regarding as fault for normal, and 'beta' stands for the chance of type II error – vice versa. As shown in Table 3, overall performances of fault detection methods which use extracted feature are quietly better than non-stationary SPC chart in type 1; however, in the case of fault type 2 and 3, feature based fault detection methods work worse than non-stationary SPC chart. It is mainly affected by the characteristic of estimator. Features, generated by ordinary least squares method, are based on the assumption of homoskedacity. Even the mean squared error is regarded as feature, homoskedacity assumption is so strong, and that leads to high beta. However support vector machine is better than \( T^2 \) method in detecting faults. Unlike other methods, support vector machine uses faulty data for training. Hence, asymptotic fault detection is expected to be done when fault detection is conducted via support vector machine.

**Table 3: The benchmark result for the detection algorithm**

<table>
<thead>
<tr>

<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>( T^2 ) with</td>
<td>.029</td>
<td>.000</td>
<td>.029</td>
</tr>
<tr>
<td>probability 0.95</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>( T^2 ) with</td>
<td>.014</td>
<td>.033</td>
<td>.014</td>
</tr>
<tr>
<td>probability 0.99</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Gaussian Kernel</td>
<td>.029</td>
<td>.067</td>
<td>.214</td>
</tr>
<tr>
<td>Inverse Multi-Quadratic</td>
<td>.029</td>
<td>.033</td>
<td>.214</td>
</tr>
</tbody>
</table>

Classification performance, shown in Table 4, is computed by this procedure. After fault detection done by \( T^2 \) method, if a signal is regarded as fault, classification is done by sequential use of support vector machine classifier. Its performance is well enough because support vector machine is able to determine tiny differences structurally. By suitable use of proper method, fault detection and classification performance could increase significantly.

<td>.029</td>
<td>.389</td>
</tr>
</tbody>
</table>

5. Conclusion

In this study, to detect the faults of cyclic signal, cubic spline regression and support vector machine fault detection and classification are presented. However, there are something remained to be properly used. First, feature selection algorithm should be enhanced. As shown in Table 3, feature selection can detect fault which has mean shift; other faults are not able to be detected easily. Assumption on homoskedacity will be the main reason of poor result of fault with high variance white noise. A feature that reflects the variance of a step should be proposed to detect faults like type 2. Also, step length should be considered as feature of a fault. Those suggestions enlarges feature dimension, however, it is expected to detect faults more sensitively.

In order to enhance the performance of support vector machine fault detection and classification, kernel selection method should be considered. Like selecting the probability in T2 method, parameters that shape kernel should be selected. However, unlike T2 method, there is no explicit relation between parameter and type I-II error. Also the parameter as penalty cost for non-separable cases should be chosen. More knowledge on the relation between support vector machine and the characteristic of signal is hoped to enhance this proposed method.

The project of a visual programming interface for the Mitsubishi Movemaster RV-M1 robot

Krzysztof Foit*, Daniel Reclik

Institute of Engineering Processes Automation and Integrated Manufacturing Systems
The Silesian University of Technology
Konarskiego 18A St.
Gliwice, 44-100, Poland

ABSTRACT
The Mitsubishi Movemaster RV-M1 is a small industrial robot with a five-axis manipulator and maximum payload of 1.2 kg. The main advantage of this robot is that it could be simply programmed using any personal computer equipped with the RS232 or the Centronics port. An operator writes a program in Movemaster Commands (MRL) language, then uploads it to the robot's controller. The controller memory is divided into two regions: one for commands and the other for positions. The positions could be programmed, verified and modified using a teaching box, but the program cannot be written or altered in this way – it is needed to use a computer. Most of available software, including the one created within the framework of scientific projects, is offered with a program editor, simulation window and even some diagnostic tools. The programming process is conducted in a standard way by writing commands and parameters. There is a lack of visual programming or creators (often called wizards) to carry on typical tasks. The aim of this paper is to present a project of the new software, which could simplify the programming process by introducing "wizards", templates for commonly used tasks and some elements of visual programming. Because the software is in the early development stage, some MRL commands have not been implemented yet.

1. INTRODUCTION
The introduction of visual programming has been a milestone in the field of application development. Manipulating elements graphically have been easier than specifying it in a textual form. On the other hand, this manner of the program description is often criticised because complicated algorithms can not be displayed in a clear form like text listing, however graphical representation is often used in systems’ modelling. This paper presents a project of a simple visual programming system intended for use with the Mitsubishi Movemaster RV-M1 robot.

The Mitsubishi Movemaster RV-M1 robot has a five-axis manipulator and is equipped with a compact control unit, which could be easily connected to any personal computer, using RS232 or Centronics port. Although the robot is quite small (the manufacturer calls it “the micro-robot system”), it is a complete, full-equipped industrial device. The complete system consists of three parts: the manipulator, the control unit and the teaching box. A typical configuration is shown in Figure 1. A personal computer (shown in Figure 1) could be any system equipped with the RS232 or the Centronics port – the first type of the port is preferred due to bi-directional transmission (the Centronics connection allows one-way communication: from a computer to the robot), however the transfer speed could be max. 9600 bps.

The memory of the robot is divided into two areas: the one for a program and the second for positions – thus the positions and the program could be changed independently. Positions can be uploaded to the robot's memory from a computer or by teaching. Every position entry has its own identification number, given by a robot’s operator, which is used in a program code. The robot could be programmed in two manners: by using a personal computer or by using a pre-programmed EPROM chip – there is no possibility of writing or change a program using a teaching box [1]. The second method is intended for infrequently reprogramming.
2. PROGRAMMING THE ROBOT WITH USE OF A PERSONAL COMPUTER

The minimum environment, required for programming with use of a personal computer is:

- any PC computer equipped with at least one RS232 or Centronics port,
- the Disk Operating System with any text editor, optionally with a high level programming language like BASIC, Pascal or C – it could be BASIC in ROM (in case of very old computers),
- a text display and keyboard – no mouse is required.

Commands could be sent to the control unit of the robot in two formats:

- without preceding line numbers – causing the immediate execution of the command,
- with preceding line numbers – causing the store of the commands in the control unit’s memory.

A program for the robot is written using Movemaster Commands [1]. Each line has the following syntax:

\[
<\text{line number}> \quad <\text{command}> \quad [\quad <\text{parameters}>]\quad .
\]

\begin{verbatim}
10 MO 10
20 DW 10,0,0
30 HE 11
\end{verbatim}

Fig. 2. A sample program written using Movemaster Commands

The Movemaster Commands are two-letter strings (abbreviations of the full name of the function), however parameters are usually decimal numbers with a preceding “+” or “-” sign. It is also possible to enter hexadecimal numbers using “&” character (for example “&2A”). An example of a program is shown in Figure 2. A program is transferred to the robot’s controller in the text form without any compilation or translation (as is). A basic problem
The project of a visual programming interface for the Mitsubishi Movemaster RV-M1 robot
during writing a program is to remember all the commands abbreviations and parameters. It is quite easy to write and execute a simple program, but developing the optimal code is more difficult, due to the mentioned problem.

The simplest method of transferring a program to the controller is to use the `COPY` command. For example, it could be entered in following manner:

```
COPY PROGRAM.ROB COM1:
```

Where `PROGRAM.ROB` is an example name of a file containing a program code and `COM1:` is the name reserved for first serial port in the system. It should be mentioned that the serial port should be earlier configured using `MODE` command.

### 2.1. The Overview of the Existing Applications Designed for RV-M1 Programming

The Movemaster RV-M1 is a product from the era when graphical interfaces were not commonly used. It has been gained popularity as a didactic machine due to its small dimensions and simplicity, but – being fully-equipped industrial machine – the robot has been also used in many scientific projects and works where high precision is required (like for example laboratory samples preparation) [2-6]. Most of the existing software has been either intended for didactic purposes or for simulation. The most known software is the COSIROP and COSIMIR packages [7]. They are commercial products with most advanced tools for programming, monitoring and simulation of the robot. The other one is Denford VR Robot intended mainly for simulation – this is also commercial software. There is also the software licensed under BSD License called JRobot [8]. It is the Java-based package developed for simulation, programming of the RV-M1 robot that also allows a remote operation and programming through a server connected directly to the robot.

A similar idea as for JRobot has been the beginning of a development of a software package at the Institute of Engineering Processes Automation and Integrated Manufacturing Systems [9,10]. It has been designed for use with the RV-M1 robot and consists of three applications: ROBO (used for programming and simulation in a virtual environment), SERWER (a network server application used for joining ROBO’s virtual environments) and KAMROB (an application which allows connecting a real robot with the virtual one in ROBO application). The main advantages of the package are:

- programming and simulation of the RV-M1 robot in a virtual environment,
- the possibility of joining virtual environments of the ROBO application working on different machines over the network and create a common workplace,
- programming the real RV-M1 and executing the commands remotely (over the network),
- remote supervision of the workplace of the real robot through an Internet camera,
- the possibility of generation of a simple program using a PTP trajectory generated in a CAD application (including a gripper status: open or close).

The software package has been developed in co-operation with the student within the framework of first and second semestral work and MSc diploma thesis. In the Figure 3, the main window of the ROBO application is shown. The aim of the package creation has been to get the software able to control a robot via Internet connection (so called “telerobot” software), using an advanced user interface and simulation tools. The RV-M1 has been an ideal machine to achieve a proper level of safety – small, lightweight and its workspace could be easily separated from the other parts of a laboratory. Due to modular structure, the software could be adapted to work with other type of robot. In the elaborated package, some elements of non-conventional programming have been introduced: the program generation on the base of a trajectory drawn in CAD software. Initially, this feature was a standalone application, now it is included in the package. It gives some advantages by generating the skeleton of the program automatically, but the advanced commands still must be entered manually.

It should be remarked that there is no software intended for the RV-M1 robot that significantly facilitates the programming process. In general, a program must be written by entering commands and parameters in a text form. It requires that the operator should be familiar with programming of the particular system. A visual programming application could improve this process in case of being an average user and could be a good tool for a novice user.
3. THE PROJECT OF A VISUAL PROGRAMMING SOFTWARE FOR THE RV-M1 ROBOT

In this section, a general concept of a visual programming environment will be presented. Furthermore, the first test version of this software will be shortly described.

The main assumption during creation of an overall conception of the software has been the simplicity of use. The second important thing has been a possibility of running the software on older computers because there is not necessary to engage a high processing power. On the other hand, newer machines do not often have the RS232 port – it is possible to use USB-serial converters, but sometimes it could cause some software problems. To achieve more flexibility and possibility of adapting the application to the other system than RV-M1, it has been decided that definitions of commands and its correspondent abbreviations will be placed in a dictionary file, compatible with any text editor.

Because of a simple syntax of the Movemaster Commands language, it has been decided that the first version of the software will not use a typical visual programming model (“boxes and arrows”), but it may be introduced in future versions. Some advanced functions have not been implemented yet. The application contains only the most used functions – mainly connected with positions, movements and the gripper. Moreover, the following assumptions have been made:

- all the functions have been divided into six groups, as it has been done in user’s manual: position/motion instructions, program control instructions, hand (gripper) control instructions, I/O control instructions, RS232 Read instructions and miscellaneous instructions,
- every function has been represented by its full name,
- every parameter has been described by its full name,
- a user interface should be as intuitive as possible,
- the process of a program creation should be done mainly by using a pointing device,
- there should be no need to do any post processing actions – it could be able to transfer a program to the robot directly from the application.

The main window of the created application is shown in Figure 4. It consists of a pulldown menu section, commands tree and two fields: one for a program and second for commands’ parameters. The pulldown menu has the standard File section, where typical commands like New, Open and Save are placed. The Transfer section contains
commands used for communication with robot: it is Upload and Download for transferring a program to and from the robot, Clear for erase the program and/or positions stored in the controller, Run for a program execution and RS232 Config for setting the basic parameters of the serial port.

![Image of visual programming application](image.png)

Fig. 4. The window of the visual programming application for the RV-M1 robot

The process of programming of the robot with use of the visual programming is conducted in the following manner:

- if it is necessary, the controller’s RAM memory could be cleared by selecting Transfer -> Clear from the pulldown menu,
- first of all it is needed to define positions – it could be done using the teaching box interface,
- next, the program could be created – it could be done by selecting a proper instruction from the tree and putting it in the program list (the upper one) by drag&drop or double click,
- the added instruction has been added on the list and marked for further edition; at the same time the parameters of that instruction will be shown on the bottom list – the values should be entered by selecting the parameter and entering values,
- after entering the last instruction the program could be saved on disk, then transferred to the robot by selecting Transfer -> Upload from the pulldown menu,
- after the upload, the program could be executed by selecting Transfer -> Run from the pulldown menu.

As it has been presented, the programming process is quite simple. The main advantage of this method is that full names of commands and parameters are used instead of incomprehensible abbreviations.
4. SUMMARY

In the paper, the project of visual programming interface for the Mitsubishi Movemaster RV-M1 has been presented. The developed application is still at the test stage and some instructions of the Movemaster Commands are not implemented yet. This concrete version of the software is intended mainly for educational purposes and it could be used during laboratory classes in order to collect users’ opinions. It is planned to introduce a package of “wizards” and templates for the most common tasks. In order to keep the flexibility of the application “wizards” should be implemented in some type of macro language. The future work will be focused on development of a better interface and functionality improvement.

ABSTRACT

Demand for plastic molded parts is on the increase in the automobile industry, since they can reduce the costs and total weight of an assembled car without lowering its structural performance. However, burrs are commonly found on the exterior of injection molded parts and these need to be removed. The burrs can be removed manually but, the manual operations are very labor intensive, require highly skilled staff and can be hazardous due to the dust that is generated. This paper presents a study on an automatic deburring system for injection molded, automobile parts, by using a 3-axis robot arm. The system is composed of a robot arm for removing burrs, a pallet and a conveyer for transferring the parts, a pneumatic clamp for fixing of the parts, and a programmable logic controller for performing the overall system control. An example is shown for injection molded parts of an automobile to demonstrate the effectiveness of the developed system.

1. INTRODUCTION

Recently, demand for plastic molded parts has greatly increased in the automobile industry because they can reduce the total weight of an assembled car without lowering its structural performance. Furthermore, the plastic molded parts can be mass-produced at lower cost, compared to other machined or forged parts. However, burrs are commonly found in injection molded parts, on their exterior, like machined ones. Note that burrs are brought about by the machining processes producing plastic deformed shapes, but they are commonly found in plastic molded parts as well. The burrs on the molded parts occur due to various causes such as high injection pressure, low bearing forces of molds, high flow rate of plastic resins, and surplus resins against cavity capacity, etc. They usually have broken, or sharp edges that could damage the contact faces of the assembled parts, as well as affecting the allowed tolerances. The burrs need to be removed while still on the shop floor and conventional manual deburring/polishing operations have been used. However, these manual operations are very labor intensive, require highly skilled staff, can be error-prone after long periods of continued duty and can even be hazardous due to the dust that is generated which consequently decreases the productivity of the shop floor.

Much research has been conducted in the development of automated deburring systems for dies and molds, which use robots and/or other transfer machines. Some researchers have focused on the prevention of burr formation: Ko [2], and Chang [3] tried to propose optimal tool paths thus avoiding the formation of burrs as well as predicting the burr
creation processes. Kim and Ko [4] presented a method of measuring burr shapes and Ko et al. [5] developed an expert system to predict burr shapes in milling operations. However, most researchers have considered the development of efficient burr removal systems, by robots or other NC systems, ultrasonic devices, electrolyzing methods, etc. Shin et al. [6], Yun et al. [7], and Ryuh and Oh [8] employed robot systems for performing deburring tasks, with sensors such as vision. Choi [8] proposed a micro deburring technology through ultrasonic vibration. Lee et al. [9] also introduced a micro-level deburring technology for sheet metals by using electrolysis and Liao et al. [10] have proposed a dual-purpose compliant tool head for automated machines to ensure stable polishing/deburring force control. This study reports the development of an economical, 3-axis robot deburring system dedicated to plastic molded parts, which is controlled through a programmable logic controller (PLC).

2. AUTOMATED DEBURRING SYSTEM

The developed robot deburring system is composed of a 3-axis, prismatic robot for burr removal, a pneumatic clamp for workpiece stability, a part transferring carriage installed on a guided rail, a conveyer for moving the parts, and finally, a PLC for controlling the entire device modules, as shown in Figure 1.

The burr removal process is as follows: A plastic molded, raw part comes to the deburring system through a part conveyer. Then, the part is moved onto a pallet by two cylinders in the carriage, being exactly aligned to a target position by a servo motor. The part is fixed with a pneumatic clamp, and the burrs of the part are removed by an end milling set in a spindle mounted on the 3-axis robot. Finally, the de-burred part is returned to the conveyer by the part transferring carriage.

![Figure 1: Block diagram of an automated robot deburring system](image)

2.1. PART CLAMPING DEVICE

Vices or jigs may cause unnecessary marks on the faces of plastic molded parts and hence a pneumatic, vacuum clamp is used for the fixing of the plastic molded parts in this system. The vacuum clamp is free from any suction marks, has a secure fast clamping operation, and maintains robust fixing without any shaking or waving during the deburring operation. Further, the clamp ensures the pre-established part location so as to reduce set-up times. Thus, the clamp has to be equipped with a jig that has the same exterior as the part, such as the cavity shape jig shown in Figure 2. Furthermore, the clamp should not interfere with the operations of the deburring robot.
2.2. **PART TRANSFERRING DEVICE**

To support consecutive burr removal operations, several pallets are required, which correspond to the supply buffers for the deburring robot. The raw parts, set in the pallets, are moved to a vacuum clamp through a transferring carriage that includes two cylinders for gripping and elevating, and a linear slider driven by a servo motor (see Figure 3). The gripping cylinder, which loads a part containing pallet, should not leave any marks on the exterior of the part, and be able to hold the part without any unnecessary, dangerous motion during the movements to the vacuum clamp. Then, the part can be moved to the clamp by the linear slider, which is a sort of servo-driven, prismatic robot.

2.3. **DEBURRING ROBOT**

The main module of the automated deburring system is composed of a 3-axis prismatic robot and a spindle holding a deburring tool, which takes away the burrs from the part fixed by a vacuum clamp. The spindle provides secure and sufficient torque and is able to withstand machining loads when removing the burrs by the installed tool, e.g. an end mill. The 3-axis robot accurately moves the tool to the deburring position through its three prismatic axes. At this point, the robot is controlled by a MAC (a multi axis controller) by Samsung Electronics. Thus, accurate and robust tool paths, as in a NC-machine, have to be determined in advance by a robot process planning module, which should be post-processed to the robot data such as the cutter location data of a NC machine. The robot tool paths should be free from the possibility of collision with other peripheral devices such as the vacuum clamp and the transferring carriage.
2.4. **ROBOT SYSTEM CONTROL**

As mentioned in section 2.1, the automated deburring system consists of three sub-modules: a vacuum clamp, a transferring linear carriage, and a deburring robot. These modules have to maintain close relationships with each other, and are controlled by a central monitoring system, i.e., a PLC. The whole system control can be represented by a ladder diagram, as shown in Figure 5.

A prototype robot deburring system, developed in this study, is shown in Figure 6, and its major specifications are summarized in Table 1.

3. A CASE EXAMPLE

In order to verify the performance of the developed prototype system, a fuel filler door from an automobile has been used as the plastic molded part for the deburring test. The part is made of ABS resin, being used for the fuel supply cap. The molded part has a burr of 1 mm thickness around its edges, as shown in Figure 7(b).

(a) A fuel filler door: finished part       (b) Burr in the edge of the part

Figure 7: Fuel filler door example

To obtain the cutter location (CL) data for the molded part, the tool path of the deburring robot is determined first. The fuel filler door has been modeled by CATIA V5.0 and 430 boundary points have been extracted from the edge of the door (see Figure 8), which is used for the CL data for the deburring tool set in the spindle of the robot system. To verify the deburring tolerance and the fixing operation of the vacuum clamp, a test operation was performed on the 3-axis machining center in advance (see Figure 9). As a deburring tool, a reverse R-end mill is used instead of a conventional formed end-mill that could cause adhesion to the cutter edge due to the heat occurring during the deburring process.
Throughout the experimental test operation, the proposed system has shown successful deburring performance and the cycle time of the developed system takes 30 seconds per part, which is an improvement of 15% in productivity over existing manual grinding operations. Moreover, from the aspect of system stability and aestheticism, the molded part is stably fixed with the vacuum pump and the machined surface is clear from the burr. Also, the developed system is able to support flexible management against changes in production as well as ensure applicability to other plastic molded parts.

4. CONCLUSION

Plastic molded parts are increasingly used as components in manufacturing automobiles since they can reduce the total weight of an assembled car without lowering the car’s structural performance. Also, they can be easily modeled by conventional commercial CAD/CAM systems but burrs on the face of the molded parts are commonly formed during the plastic injection molding processes, because of the injection molding conditions and the defects of the dies that are employed. In most cases, burrs are removed through manual grinding operations that decrease the productivity on the shop floors. Furthermore, the manual operations can often result in musculoskeletal disease of workers.

For the automatic deburring of injection molded parts, a prototype system has been developed in this study, which comprises a 3-axis prismatic deburring robot, a transferring carriage, a vacuum clamp, and a PLC for performing the overall system control. The transferring, clamping, and deburring operations have been verified through a test operation carried out on a 3-axis machine center, and the test results have shown successful performance with economical devices and tools, compared to existing 6-axis based, deburring robot systems, or other dedicated or compliant tool head based commercial equipment [11]. In particular, the developed system, presently used in a local company, has shown a 15% improvement in productivity over existing, manual grinding operations for the tested part. Further development underway includes the integration of the proposed system with an automatic, exterior data inspection system.

Obstacle and Collision Avoidance in Unstructured and Time-Varying Environments: A Screw Theory Approach for Manipulators

Carlos R Rocha*, Henrique Simas, Daniel Martins, and Altamir Dias

Department of Mechanical Engineering
Universidade Federal de Santa Catarina
Florianópolis, SC, 88040-900, Brazil

ABSTRACT

Robots are increasingly being used in applications where they are required to operate in unstructured or poorly mapped environments. Eventually, these environments can change over time, as in case of objects or people entering the robot’s task space. In many cases, human and robot safety issues are of concern, since there will be human-machine interaction. In those, obstacle and collision avoidance are of major concern, to prevent injuries to people and possible damages to the equipment involved. Introducing kinematic redundancy in the mechanical structure of the manipulator increases dexterity, allowing it to execute tasks while complying with complementary objectives, such as avoiding singularity, operating within joints/actuators limits and obstacle/collision avoidance. However, redundancy turns the resolution of inverse kinematic into an infinite solutions problem. This work presents a solution to the problem above, based on the screw theory, the Kirchhoff-Davies method to solve differential kinematics in closed-loop kinematic chains, and the use of virtual chains to define the task to be executed and to model the obstacles to be avoided. It will be presented an example of the use of these techniques to solve the inverse kinematics problem involving redundancy to achieve obstacle avoidance. Finally, the extension of the technique to avoid collision with moving obstacles or unstructured environments will be discussed.

1. INTRODUCTION

Industrial manipulators usually operate in structured and isolated workspaces, in order to avoid collision, which could damage materials and equipment, and also cause injuries to humans. This reality is gradually changing, as manipulators are increasingly being used in new applications, which are not only restricted to the usual safe workspace. In these applications, the environment is not necessarily known a priori, and it may be time-varying, with obstacles moving through the workspace. It could even interact directly with human beings, eventually. The ability to autonomously operate in this kind of environment is a key feature to intelligent robotic systems [1]. Several examples of these applications are presented in literature. Among others, it could be noted the human/robot interaction, where a collision could severe injury a human, and safety issues are especially important [18].

To guarantee integrity of all elements present in the workspace, it is fundamental to have collision avoidance strategies, with obstacle detection/deviance while the manipulator executes the task assigned. In this work, obstacles are defined as entities placed in the workspace, which contact with the manipulator is undesirable. It is also considered that collision may occur in any link of the manipulator kinematic chain, and not only in the end-effector.

In a completely structured known environment, it is possible to map all collision possibilities, which can be monitored and modeled, being part of the system model. Cheung calls this approach The Piano Movers Problem [3].

However, in the most general case, the information about the environment is assumed to be incomplete, and environment itself cannot be considered static. In this situation, it is necessary to use sensors to gather environmental information during the task execution. These sensors must cover not only the possibility of collision with the end-effector, but also that the collision can occur in any link of the manipulator. Several authors discuss this problem,

* Corresponding author: Tel.: +55(53) 9971-3148; E-mail: cticarlo@gmail.com , cticarlo@furg.br
using different approaches and sensor types to solve it [1,3-5]. Lumelsky discuss the requisites and uses of a sensitive skin, and its importance to intelligent robots operating in non-structured environments [6].

Obstacle avoidance implies additional constraints to the task to be executed. In this case, it is necessary to have redundant degrees of freedom to accomplish the task [7-8]. In this work, redundancy means kinematic redundancy, defined as the difference between the degrees-of-control and the connectivity between two links of a kinematic chain by Martins and Piga-Carboni [9]. In a simpler way, redundancy occurs when the mobility of the kinematic chain is greater than the necessary in order to the manipulator execute a task. It can be noted that redundancy can depend on the type of the task to be executed [8].

Redundant manipulators have increased dexterity, allowing the addition of complementary goals to the primary task, such as avoiding obstacles, singularities and joints/actuators limits, and to optimize performance criteria. Having an infinite number of solutions, the inverse kinematics problem allows specifying additional constraints to represent the complementary goals cited. Several authors have proposed methods to solve the inverse kinematics problem in redundant manipulators, using pseudoinverse jacobian, task augmentation or task priority, to cite some techniques. A discussion of these more usual techniques is made in [8]. In this work, it will be used the kinematic constraints method, which is based on screw theory, the Kirchhoff-Davies method and the use of virtual chains, as presented in [10-12]. Among other features, this method does not operate with dimensional inconsistencies, and has the property of conservative movement [12].

In the next section, the fundamentals of the kinematic constraints method will be presented. Section 3 will present an example of the use of this method, in a static ambient and a known obstacle. The extension of the technique to an unstructured, time-varying environment will be discussed in section 4, where the use of sensors to identify obstacles, the strategies to select the proper kinematic model in each state that the robotic system can be while executing a task, and problems related will be addressed. Section 5 will present the conclusion.

2. BACKGROUND

The kinematic constraints method is based on screw theory. It uses virtual chains to impose movement to the manipulator, to monitor and to define complementary kinematic constraints as well. The Kirchhoff-Davies method defines differential kinematics constraints between the links of a closed kinematic chain. In order to obtain joint position values, it is necessary the integration of the inverse differential kinematics obtained by use of the Kirchhoff-Davies method, which results in drift, caused by the numerical method used. The kinematic chain then opens, resulting in errors. The addition of error virtual chains allows to control and to minimize drift. This section will present shortly these fundamentals. Fontan and Simas have detailed and exemplified explanation in their work [11-12].

2.1. Screw Theory

Screw theory is a tool for static and kinematic analysis of mechanisms. It was first formulated by Mozzi, in 1763, and it was systematized by Ball in 1900. Later, Hunt and Tsai applied this theory in static and kinematic analysis of mechanisms [10]. A screw is a geometric entity composed by a directed line and a pitch, which can represent rigid body movements, according to Chasles Theorem [13-14].

Consider a point P, moving from a position P_i to a position P_2. The movement can be described by a rotation around a directed line, followed by a translation parallel to that line, as shown in Figure 1. The magnitudes of rotation and translation are related by a pitch h. Based on this representation, the movement can be represented by four parameters, which are an unitary vector parallel to the screw axis (s), a position vector to a point belonging to the screw axis (s_0), the value of the rotation around the screw axis (θ) and the magnitude of the translation parallel to the screw axis (r). With these four parameters it is possible to calculate a homogeneous transformation matrix [13]. As in Denavit-Hartenberg notation, it is possible to combine successive displacements applied to a rigid body, caused by the joint movements in a kinematic chain multiplying the corresponding homogeneous transformation matrices.

A twist represents the instantaneous movement of a rigid body relative to a referential system. It can be defined as \( \mathbf{s} = (\omega, \mathbf{v}) \), where \( \omega \) is the angular velocity of the body and \( \mathbf{v} \) is the linear velocity of a point in the body instantaneously coincident with the origin \( \mathbf{O} \). \( \mathbf{v} \) has a component normal to the twist axis and another component parallel to this axis. The twist can be represented by a normalized screw \( \mathbf{s} \) multiplied by a magnitude \( \dot{\gamma} \), as shown in Equation (1).
In a kinematic chain, a twist can represent the movement of a link relative to its predecessor. It is common, in robotics, the use of prismatic and rotational joints, which simplifies the normalized screw associated with the joints, since the pitch is equal to 0, when a joint is rotational, and it is equal to ∞ when a joint is purely translational. In Equation (2), $\mathbf{s}_r$ is a normalized screw for pure rotation, while in Equation (3) $\mathbf{s}_t$ is a screw for pure translation.

$$\mathbf{s} = \mathbf{S} \dot{\mathbf{q}} = \left[ \mathbf{s} \right]_{\mathbf{k}}$$

In Equation (4), $\mathbf{S}_l$ is the Jacobian mapping joint displacements to link movements in inertial coordinate system.

$$\mathbf{S}_l = \sum_{i=1}^{l} \left[ \mathbf{s}_i \right]_{\mathbf{k}} = \sum_{i=1}^{l} \mathbf{s}_i \dot{q}_i$$

Equation (4) can be rearranged to group normalized screws and joint variables, resulting in

$$\mathbf{S}_l = \left[ \mathbf{s}_1 \dot{q}_1 \quad \cdots \quad \mathbf{s}_l \dot{q}_l \right]^T = \mathbf{N} \mathbf{q}$$

2.2. THE KIRCHHOFF-DAVIES METHOD

Davies adapted Kirchhoff’s circulation law to the case of closed kinematic chains, in order to analyze its differential kinematics [10,12]. In his work, he stated that “the algebraic sum of the relative velocities of kinematic pairs in a closed chain is equal to 0” [15]. This adaptation allows to define a constraint equation to a closed kinematic chain, relating its joint velocities [12].
A simple example can be used to illustrate this method. Consider the four-bar linkage depicted in Figure 2. Joint A is actuated, while the others are passive. Since it is a planar linkage, the screw system order is three, having two linear components in $x$-$y$ direction and an angular component around the $z$ direction. The components of the normalized screw will be $N, \vec{P}$ and $\vec{Q}$ [12]. Using the Kirchhoff-Davies method, the sum of the joint velocities is zero, as shown in Equation (6), where $\mathbf{s}_i$ is the twist relative to joint $i$, and $\mathbf{0}$ is a column vector, with dimension equal to the screw system dimension.

$$\mathbf{s}_A + \mathbf{s}_B + \mathbf{s}_C + \mathbf{s}_D = \begin{bmatrix} \dot{s}_A \\ \dot{s}_B \\ \dot{s}_C \\ \dot{s}_D \end{bmatrix} \begin{bmatrix} \dot{q}_A \\ \dot{q}_B \\ \dot{q}_C \\ \dot{q}_D \end{bmatrix} = \mathbf{0}$$ (6)

Equation (6) can be rewritten as

$$\mathbf{N} \dot{\mathbf{q}} = \mathbf{0}$$ (7)

To solve this system and obtain the passive joints velocities, Equation (7) can be rearranged, partitioning the twists into primary (which magnitudes are known) and secondary ones (which magnitudes have to be obtained), as shown in Equation (8).

$$\begin{bmatrix} \mathbf{N}_p \\ \mathbf{N}_s \\ \mathbf{0} \end{bmatrix} \begin{bmatrix} \dot{q}_p \\ \dot{q}_s \\ \mathbf{0} \end{bmatrix} = \mathbf{0}$$ (8)

The secondary joints values will be determined by Equation (9), if $\mathbf{N}_s$ is invertible. Otherwise, the system will be in a singularity [10].

$$\dot{q}_s = -\mathbf{N}_s^{-1} \mathbf{N}_p \dot{q}_p$$ (9)

Graphs are a very useful tool to analyze kinematic chains, specially closed ones, and it eases the Kirchhoff-Davies equations definition. Tsai explains in detail the use of graphs to kinematic analysis of mechanisms [13,16].

### 2.3. Virtual Chains

Campos defines a virtual chain as a kinematic chain used to observe and obtain information about real kinematic chains, and also used to introduce constraints/movements to the real chains [10]. A virtual chain must be: a) a serial chain; b) the twists representing joints displacements must be linearly independent; c) it can not modify the mobility of the real chain [11,12].

In planar case, virtual chains must have mobility equal to three, in order to comply with the characteristics [10]. Most common are PPR chains, composed by 2 links connected by a prismatic joint, with one end having a prismatic joint and another end having a rotational joint, and RPR chains, which differ from the latter by having rotational joints in both ends. PPR chains (Figure 3.a) can be associated to Cartesian coordinate systems, while RPR chains (Figure 3.b) can be associated to polar coordinate systems.

In spatial configurations, virtual chains must have mobility equal to six, and PPPS chains, which can be associated with Cartesian coordinate systems, are common (Figure 3.c).
In order to use the Kirchhoff-Davies method, a kinematic chain must be closed. In serial manipulators, virtual chains can be used to close the overall chain. Virtual chains can be also used to monitor certain movements, as the case of observing proximity of a link to an obstacle. Another use of virtual chains is the definition of constraints to the movement, which could be very useful in to solve inverse kinematics in redundant chains.

Figure 4.a depicts an example of closure of a serial chain of a planar manipulator, where a PPR virtual chain is used to impose end-effector position. Figure 4.b depicts a RPR, used to monitor the proximity of an obstacle. In spatial configurations, the use of virtual chains is analogous. Fontan presents several examples of the use of virtual chains, applied to serial and parallel mechanisms [10].

2.4. INVERSE KINEMATICS RESOLUTION

By using virtual chains to impose the movement, the Kirchhoff-Davies method can be used to solve the differential inverse kinematics, considering the virtual joints as primary and the real joints as secondary. Some care must be taken to choose secondary joints, in order to obtain an invertible $N_s$ matrix. With known joint velocities, it is possible to obtain the joint displacements, through integration of the joint velocities over time. Numerical methods are usually employed, since the analytical resolution is very complex in most cases [10-12].

Numerical methods generate drift, resulting in position errors. In closed chains, those errors will imply in chain opening. Simas propose one solution to this problem in [12], by addition of error virtual chains, to monitor drift effects and to minimize closure errors.

With the modifications, the new kinematic chain is described by Equation (10), where $N_e$ and $\dot{q}_e$ are added, corresponding to the error normalized screws and to the variation rates of error, respectively.

$$
\begin{bmatrix}
N_p & N_s & N_e \dot{q}_p & \dot{q}_s & \dot{q}_e
\end{bmatrix}^T = 0
$$

(10)
The velocities of the secondary joints are obtained by Equation (11), where $q_e$ corresponds to the positions of the error virtual chain and $K_e$ is a positive definite gain matrix.

$$\dot{q}_e = -N_s^{-1}N_p \dot{q}_p - N_s^{-1}N_e K_e q_e$$

(11)

Simas analyzes and exemplifies the procedure, proving the stability of this method [12].

3. Case Study

To illustrate the method, consider the RRRR planar manipulator shown in Figure 5. The second link may collide with an obstacle, and the proximity will be monitored. In this example, two virtual chains are used. The positional PPR virtual chain imposes the movement to the end-effector, while the obstacle RPR virtual chain is used initially to monitor the proximity between the second link and the obstacle. The primary joints, in the monitoring state, are $p_x$, $p_y$, $r_z$, and $D$, while the secondary joints are $A$, $B$, $C$, $r_z1$, $r_z2$, and $p_x$. $D$ was chosen arbitrarily, to define an invertible matrix $N_s$. The $p_r$ joint is used to monitor the obstacle. When its position value is below a pre-established threshold, the manipulator will change to collision avoidance state.

In this state, the kinematic model will be modified, in order to impose a constraint represented by joint $p_r$. This joint will be considered a primary one, while joint $D$ will be turned into a secondary one. Joint $D$ will be actuated, in order to achieve a configuration where the task can be performed while avoiding the obstacle.

![Figure 5: RRRR manipulator in presence of obstacles](image)

When the value of the value position of $p_r$ is over the threshold, the manipulator changes its state to monitoring, and the kinematic model turns back to the first specified. To simplify the example, the error virtual chains were not included, but they are essential to solve the inverse kinematics. A similar example is presented in detail in [11], where a PRRR planar manipulator is used, and a spatial case, with experimental results, is analyzed.

4. Extending the Technique to Use in Unstructured and Time-Varying Environments

According to Cheung and Lumelsky, a manipulator must have a trajectory planning system based on sensors, in order to operate in unstructured and/or time-varying environments [3]. It is necessary the ability to identify possible contact with obstacles with any part of the manipulator, and it is necessary to have the capacity to rapidly process large quantities of sensorial information, in order to achieve local modification of the global trajectory planned. This area of research is very active, with various approaches in the use of sensors and strategies of adaptation. In common, it can be noted the consideration of a kind of sensitive aura over the manipulator structure, inside which the space can be considered free of collision. As the manipulator moves, the aura moves with it. When some obstacle contacts this aura, its position relative to one or more sensors is determined, and a strategy to avoid collision is taken.

It can be considered that it is possible to detect the proximity of an obstacle, and its position relative to some part of the manipulator, the same way that monitoring using virtual chains. The virtual chain can be used only to constraint the movement in order to avoid collision, leaving the detection and monitoring to sensors.
There will be different states during the execution of a task, according to Fontan [11]. In the free movement state, one kinematic model will be used, where redundancy can be used to optimize some criteria, or to limit the actuation of some joint. In collision avoidance state, another kinematic model will be used, where virtual chains to constraint the movement will be used. Depending on the sensor, several collision avoidance strategies can be used, depending on the type of the obstacle identified. The IPA sensor presented in [5], for instance, can be used to map several points, which could be used to estimate the shape of the obstacle and to use a virtual chain more adequate to each case.

One problem with the model switching is the possibility of discontinuities in the movement, with undesirable effects over the joints and the actuators. Fontan and Santos discuss this problem, proposing some strategies to reduce the discontinuities during switching. This problem can be more relevant when the environment changes over time, because of the continuous and uncertain switching [11,17].

Another situation to be considered is how to handle the presence of multiple obstacles, and the strategies related. The example presented only one possibility of collision. In some cases, the same approach may be used with more obstacles, if it could be considered that only one obstacle is in proximity of collision at any time. But if various obstacles are in imminent collision, the strategy must be modified. Some authors developed strategies to handle this possibility, and it is necessary to determine how to handle that problem with virtual chains [3,5].

5. CONCLUSION

This work presented a technique used to avoid collisions with obstacles of a manipulator operation in a structured environment, and discussed the characteristics necessary to extent the technique to the case of an unstructured and time-varying environment. To avoid obstacles while executing the task assigned to it, the manipulator has to be redundant, and to solve its inverse kinematics the kinematic constraints method is used. It was presented the fundamentals to this method, which is based on screw theory, the Kirchoff-Davies method and virtual chains.

When executing a task where obstacles must be considered, the kinematic model of the robotic system may vary, depending on the operating status (needing to avoid an obstacle or freely operating), which demands a decision-making algorithm that will choose the appropriate kinematic model at each instant of the task execution.

It was discussed how to extend the technique to use in unstructured and time-varying environments, where sensor information is needed. The sensors must cover all surface of the manipulator, developing a kind of sensitive skin. When the sensitive aura contacts an obstacle, sensors provide information about the position of the obstacle relative to a link, and the kinematic model is modified, in order to consider the constraint needed to avoid collision with the obstacle. Different strategies can be implemented, depending on the obstacle type and the information obtained from the sensors. The proposed extension discussed will need further work, and results will be presented in future papers.

Finally, it is considered that another contribution of this work was the definition of obstacle and collision, in the context of the robotic manipulation tasks.

An Experimental Analysis of Bernoulli End Effectors for Contact Manipulation of Irregularly Shaped Objects

Nebojsa I. Jaksic* and Gajendiran Mohandass

Engineering Department
Colorado State University - Pueblo
Pueblo, Colorado, 81001, USA

ABSTRACT

Bernoulli end effectors or Bernoulli pickups are manipulating devices that use the Bernoulli effect to perform contactless manipulation of flat parts. They are often used for handling silicon wafers during the manufacturing of integrated circuits. In general, a Bernoulli end effector consists of a flat plate with a through hole placed in the center of the plate and connected to a positive pressure fluid source. To operate, the plate is placed close to a flat part to be manipulated, and then fluid is allowed to flow out of the hole and into the space between the plate and the part. This fluid flow creates a low-pressure zone which in turn creates an attractive force between the part and the plate enabling levitation of the part near the plate.

In this experimental study, a number of tests are performed to optimize the lifting capacity of Bernoulli end effectors in contactless mode. The lower flat surface of the plate of a Bernoulli end effector is changed into a conical surface with the center at the center of the hole. An optimal cone angle, discovered experimentally, increases the lifting capacity of the end effector about 20%. Additionally, a novel application of Bernoulli end effectors dealing with manipulation of irregularly shaped objects in contact with the end effector is analyzed. A number of experiments are performed to illustrate the versatility of these devices. The same Bernoulli end effector is used in contact mode to manipulate plastic bottles in various orientations as well as rocks. An advantage of using Bernoulli end effectors in contact mode instead of in contactless mode is illustrated by tilting an object from 0 to 90°. This is not possible in contactless mode since the low friction allows the object to slide off the plate when tilted.

1. INTRODUCTION

The scope of traditional end effectors like mechanical grippers or vacuum pickups is limited by the size, geometry, weight, and other physical characteristics of the manipulated objects. Industrial manipulators equipped with specialized robotic grippers are well suited to pick-and-place tasks in applications where the physical characteristics of manipulated objects are similar [1]. However, a simple change in object size or material may require a change of the gripper. Also, handling large, flat, non-rigid, or delicate parts is not easily accomplished with many standard grippers. Vacuum pickups used as end effectors further extend the range of objects a robot can manipulate. However, they rely on vacuum created between one or more suction cups and the manipulated object. If a sufficient vacuum cannot be established between the vacuum pickup and the object, then the object can not be manipulated. This is the case with porous objects or irregularly shaped objects where the objects’ surface characteristics do not allow creation of vacuum between the suction cups and the objects.

A Bernoulli end effector or a Bernoulli pickup is a pressurized fluid device capable of picking up objects by creating a difference in pressure between the surface of an object and a surrounding medium caused by the flow of fluid (most applications use air) between the object and the device. The main advantage of using Bernoulli end effectors is that they can perform contactless manipulation of parts. However, they are limited to mostly flat parts, so they are often used to contactlessly handle integrated circuit wafers in different stages of integrated circuit production [2-8], to manipulate large flat lithographic plates in the printing industry [9], and to manipulate hot glass...
sheets in the production of vehicles [10]. Here, after redesigning Bernoulli end effectors to maximize their lifting force, a novel mode of operation is introduced that greatly expands the capabilities of these devices.

2. Previous Work

This study of Bernoulli end effectors was inspired by a practical problem in an air jet based active tooling for vibratory bowl feeders [11]. When an air jet was used to reorient small parts in a vibratory bowl feeder, regardless of the air jet pressure, a number of parts failed to reorient when the pressurized air was applied against them. The airflow between the bowl wall and a part created an attractive force between them large enough to actually press the part against the bowl wall. The slight curvature of the bowl wall increased this attractive force. This problem caused by the Bernoulli effect was solved empirically by separating the parts from the bowl wall by mechanical means. The separation distance was also determined experimentally.

A classification of contactless part manipulation using different levitation techniques is presented in [12]. In fluid mechanics literature [13, 14], Bernoulli end effectors are described as examples of axi-radial flow or diverging radial flow. Paivanas and Hasan [14] assume one-dimensional, steady, laminar, incompressible flow conditions for diverging radial flow between two parallel closely spaced disks. Their theoretical results on spatial pressure distribution and resultant disk force closely match experimental findings except in the region where the axial flow changes into radial. Erzincanli and Sharp [15] propose Bernoulli end effectors for non-contact manipulation of non-rigid materials like food products, while design and operational considerations of Bernoulli end effectors are presented in [16]. A simplified force analysis assuming flow conditions as in [14] using a modified Bernoulli end effector comprising a deflector and a set of axially placed ribs is presented in [17] where the end effector is used for contactless manipulation of sliced tomatoes and cucumbers. Pressure distribution, air velocity, and the gap size are calculated using momentum conservation and common friction factors under assumptions of turbulent and compressible flow [18]. Vortex levitation devices using swirling air flow are proposed as a variation on Bernoulli end effectors in [19].

3. Principles of Operation

Figure 1 depicts perspective and front views showing a typical Bernoulli end effector handling an object having at least one flat surface facing but not touching the plate of the end effector. Figure 2 presents perspective and front views showing a Bernoulli end effector handling an irregularly shaped object. The end effector consists of a gas-carrying tube with a nozzle attached to the center of a plate. The bottom surface of the plate is flat.

To manipulate an object, a Bernoulli end effector is placed close to the object or in contact with it. Then, a gas flow is established through the tube and out of the nozzle of the Bernoulli end effector. The pressure of the gas directly hitting the object creates a force pushing the object away from the end effector. This force is prevalent when the object is at least a few millimeters away from the end effector. However, when the object is closer to the end effector, the radially moving air creates a negative pressure differential between the plate of the Bernoulli end effector and the object creating an attractive force between the two (the Bernoulli effect). For the correct operation of the device, this force (actually the difference between the Bernoulli effect force and the pushing force) must be high enough to move the object when the end effector is moved. The gap between the plate and the object remains during object manipulation allowing non-contact manipulation of the object by the Bernoulli end effector. At the end of the manipulation, the object is released from the end effector by switching off the gas supply to the tube.

During non-contact manipulation of an object, the manipulated object has at least one flat surface facing but not touching the plate of the end effector. During the manipulation of an object when the manipulated object is an irregularly shaped object, the object is in contact with the end effector. Either concave or convex object surfaces can be in contact with the end effector. As an additional advantage, the presented process can manipulate objects having porous or solid surfaces in both the contact and non-contact modes.
An Experimental Analysis of Bernoulli End Effectors for Contact Manipulation of Irregularly Shaped Objects

By adjusting one or more process conditions such as the mass flow of gas, the bottom plate surface type, shape and area, the nozzle shape and dimensions, etc., the process can be optimized for maximum attraction force between the plate and the object. The desired force distribution on the object can also be designed.

The air flow between the lower plate surface and the object surface facing the plate is turbulent and compressible in a region radially close to the nozzle. According to [17] and [18], the resultant force between the plate and the
object depends on the pressure at the nozzle, the cross sectional area of the nozzle, the size of the gap, the radial dimension of the plate, the square of the radial velocity of the air, the air density, the friction factor [20], and the air viscosity.

The forces occurring during the manipulation process are analyzed qualitatively. As the air flow is established between the object and the end effector plate an attractive resultant force starts acting on the object. At the moment the object is pulled vertically towards the plate of the Bernoulli end effector, the attraction force between the end effector and the object is larger than the weight of the object. This accelerates the object towards the end effector plate. If the object is sufficiently far from the plate the attractive force increases since the gap decreases thus increasing the air velocity. However, as the gap decreases further, the effects of friction increase slowing the air, thus decreasing the resultant attractive force. At some gap size the average attractive force becomes equal to the object weight resulting in object levitation.

In the case of contact manipulation, an object is pulled towards the end effector plate with a force larger than its weight. The gap size is determined by the geometry of the object. Additionally, the created contact allows objects to be tilted since there is friction between the end effector and the object. In the next section, a few process variables will be analyzed experimentally. Also, the versatility of this end effector will be demonstrated by a few representative examples.

4. EXPERIMENTAL RESULTS

In this section, two experimental setups are described. Experiments in contactless and contact mode are performed to study the effects of plate surfaces (surface shape, roughness, etc.) on the maximum attractive force between the plate and the manipulated objects. A few applications illustrating the advantages of Bernoulli end effectors over other end effectors are highlighted.

4.1. EXPERIMENTAL SETUP

There are two experimental setups constructed for this study. The first setup uses a Bernoulli end effector mounted on a stand via a fixture. The height of the Bernoulli end effector can be adjusted by sliding the fixture up and down the stand. Once the desired height is reached the Bernoulli end effector can be fixed in the desired position by a screw on the back of the fixture. The end effector is further connected to shop air via a filter lubricator regulator (FRL) unit, a pneumatic on/off valve, and a pneumatic tube. The regulator is adjusted to a desired air pressure. Two aluminum, 150mm x 150mm x 15mm, rectangular plates are used, one with a flat bottom surface and the other with a concave bottom surface. In the second setup, two 140 mm-diameter cylindrical plates (one with a flat bottom surface and the other with a concave bottom surface as shown in Figure 3) are used without the stand to test friction effects in contact mode.

4.2. EXPERIMENTAL SET 1: CONTACTLESS MANIPULATION STUDIES

The following examples describe non-contact manipulation of objects that have at least one flat surface. The experimental setup with the stand is used. According to Figure 1, the end effector is placed at the top of and close to the object to be manipulated. The gap size between the plate surface and the flat surface of the manipulated objects is
An Experimental Analysis of Bernoulli End Effectors for Contact Manipulation of Irregularly Shaped Objects

in the order of 1 mm. Then, by switching the pneumatic valve on, pressurized air is applied through a 6.35-mm inner diameter gas-carrying tube of the end effector. By varying the air pressure from 280 kPa to 550 kPa, cylindrical objects of various sizes and weights (from 180 to 1200 grams) are lifted.

Then, the Bernoulli end effector is modified to maximize the force between the bottom surface of the plate and the manipulated objects. The bottom surface of the plate is modified in such a way to create a concave surface of various concavity angles. The angles of concavity from 0º to 9º in increments of one degree are investigated. To create these concave surfaces, the aluminum plate of previous runs is secured in a lathe and a shallow cone at an angle of about 1º with respect to the original flat bottom surface is cut out from the flat bottom surface. The cone vertex is in the center of the plate and the center of the nozzle. Then, this plate is used to lift objects of various weights at various pressures. The process with a modified plate up to about a 9º-cone cutoff is investigated. The maximum force is obtained for about a 3º angle of concavity. In this case, by varying the air pressure from 280 kPa to 550 kPa the end effector is able to lift cylindrical objects from 230 grams to 1400 grams - resulting in a 20% increase in lifting capacity.

The velocity of the air changes from axial (straight down) to radial (horizontal) as the air hits the object. Assuming the velocity vector only changes the direction, and assuming conservation of mass flow, the area of the nozzle and the cylindrical area just outside the nozzle and between the end effector and the object must be equal, i.e.

\[
\pi r_0^2 = 2\pi r_0 h_0
\]

where \( r_0 \) is the radius of the nozzle and \( h_0 \) is the starting gap size. From Equation (1) the starting gap size is

\[ h_0 = r_0 / 2. \]

Calculating starting gap sizes from the concavity angles of 2º, 3º, and 4º for a 140 mm-diameter Bernoulli end effector leads to 2.45 mm, 3.67 mm, and 4.88 mm starting gap sizes, respectively. However, calculating the starting gap size of the experimental setups using Equation 2 is not straightforward since the nozzle is only partially threaded into the end effector plate. This means that the nozzle is not in the plane of the plate. It is recessed about 5 mm. The outer radius of the nozzle is 9 mm. So, for \( r_0 = 9 \text{ mm} \), \( h_0 = 4.5 \text{ mm} \). This result matches (within the resolution of the experiment) the experimentally obtained starting gap size for maximum resultant force.

Another set of experiments is performed to investigate the effect of the surface finish of the bottom surface of the end effector plate on the force between this surface and the manipulated objects. End effector operations with the aluminum plate used previously having a rough surface, a machined surface, and a manually polished surface are compared. The manually polished surface exhibits the highest force confirming that friction cannot be neglected.

To prove the capability of the described Bernoulli end effector to manipulate porous objects, a 216 mm x 115 mm piece of Vector Electronic Company punchboard with 1 mm diameter through holes arranged in a grid with a hole-density of 16 holes per cm² is successfully lifted.

4.3. EXPERIMENTAL SET 2: CONTACT MANIPULATION OF IRREGULARLY SHAPED OBJECTS

This example describes the manipulation of irregularly shaped objects using a Bernoulli end effector in the contact mode. As in previous examples, the end effector of Figure 2 is connected to shop air via an FRL unit, a pneumatic on/off valve, and a pneumatic tube. The regulator is adjusted to a desired air pressure. The end effector plate, with dimensions of 150mm x 150mm x 15mm, made of aluminum and having a flat bottom surface is mounted on the stand. According to Figure 2, the end effector is placed on the top of the object to be manipulated. Then, by switching the pneumatic valve on, pressurized air is applied through a 6.35 mm inner diameter gas-carrying tube. In this example, a number of irregularly shaped objects of various shapes, weights, and sizes are manipulated. The force created between the bottom surface of the plate and the object due to the Bernoulli effect allows manipulation of the object by moving the end effector. In addition, irregularly shaped objects from about 100 grams to about 200 grams can be tilted from 4º to 11º using air pressures from 280 kPa to 550 kPa.

When a concave surface having a concavity angle of about 3º is used as the bottom surface of the end effector plate, the force between the bottom surface of the plate and the object is increased. During manipulation, irregularly shaped objects from 100 to 200 grams can be tilted from 10º to 35º using air pressures from 280 kPa to 550 kPa, which is about a 24º increase in performance at high pressures, or 300%. 

Page 448
4.4. APPLICATIONS

Contrary to the current opinions on the limited uses of Bernoulli end effectors, Figure 4 illustrates the wide range of objects that can be manipulated with these devices. In Figure 4, a 45.7 gram plastic bottle is manipulated in the contact mode. The bottle is picked up from all possible sides, on the side as shown in Figure 4a, from the top as shown in Figure 4b, and from the bottom as shown in Figure 4c. For “grabbing” the bottle on the side and the bottom a pressure of about 140 kPa is used. Since there is a rather limited surface area on the top of the bottle, for “grabbing” the bottle from the top a somewhat higher pressure of 180 kPa is applied. It is interesting, in this example, that all contact surfaces are convex. Next, figure 4d depicts a view of a rock (an irregularly shaped object) manipulated by the Bernoulli end effector. The rough surface of the rock would present a problem for vacuum chucks, and its irregular shape would pose a problem for many mechanical grippers. Picking the bottle from the top would also be difficult for many classical end effectors.

![Figure 4: Bernoulli end effector applications: (a) holding a bottle in a horizontal position; (b) holding the same bottle in an upright position; (c) holding the bottle upside down; (d) holding a rock](image)

Advantages of the contact mode of manipulation over the contactless mode are illustrated in Figure 5. The plastic bottle is tilted about 60° as pictured in Figure 5a and 90° as depicted in figure 5b. In contactless mode, since the manipulated object is resting on an air cushion there is little friction between the end effector and the object. This
means that objects could slip easily from the end effector. In contact mode, the Bernoulli attractive force acts like glue holding the object against the plate of the end effector.

Figure 5: Bernoulli end effector application: (a) tilting a bottle approximately 60º, (b) tilting a bottle 90º

5. SUMMARY

Bernoulli end effectors are analyzed experimentally. A novel contact mode of operation is described and justified. The maximum lifting force of these end effectors, in both contact and contactless modes, is increased about 20% experimentally by turning the flat plate into a cone with a 3º-concavity angle. The range of objects that can be manipulated with Bernoulli end effectors is greatly expanded. This work illustrates and justifies additional advantages of Bernoulli end effectors over their mechanical counterparts in that they can manipulate a wide variety of objects without the need for complicated apparatus or retooling; they can manipulate objects having at least one relatively flat surface without contact with the end effector; they can manipulate objects having porous or rough surfaces; and, in contact mode, they can manipulate and tilt irregularly shaped and/or porous objects having concave, convex, and/or flat surfaces.

ABSTRACT

Radio Frequency Identification (RFID) is an AIDC technology that is used to identify people or objects carrying encoded microchips through the use of radio waves. RFID technologies were initially developed by the British military in the 1940s in order to be able to distinguish their own aircraft from the enemy aircraft by equipping the aircraft with devices to send out coded signals. RFID technologies have since found applications in many everyday devices such as remote controls for gates or garage doors, anti theft devices in vehicles, security systems and the new European Union passport as well as becoming widely used within the manufacturing industry to allow information to pass easily and accurately between different stages of the supply chain. RFID technology has been successfully implemented within many large multinational organisations but research into the successful implementation of RFID systems within SMEs is far more limited.

An investigation was conducted at a Teesside manufacturing SME to identify the areas in which the implementation of an RFID system would benefit the company through improved efficiency and visibility of the processes and also the accuracy and reliability of real-time data transfer. An exploration of various RFID systems and their function within the manufacturing environment was undertaken so as an appropriate technology could be identified that may be suitable for implementation within the SME to improve the manufacturing process. The investigation of a feasible AIDC technology is then outlined and the determination of whether this technology may add value to the current operations at the SME is analysed. The possible limitations of the success of an RFID system and also any problems that may occur either during implementation stage of for future performance were identified alongside the perceived benefits for the company including a cost benefit analysis.

1.0 INTRODUCTION

In the manufacturing industry, the tracking of a product and its status through the processes of a company, from the moment it arrives until the time of despatch, can significantly reduce the lead time, increase the efficiency and visibility, increase the accuracy of production plans and also improve the efficiency of an Enterprise Resource Planning (ERP) system. As the constant demand for total visibility and fast and accurate information flow increases, the inefficiencies of traditional systems are becoming more apparent. [1]

Automatic Identification and Data Capture (AIDC) technologies and systems were initially developed as a response for the requirement to collect and transfer levels of data in an efficient, quick and accurate manner. AIDC technologies can reduce or even eliminate the occurrence of errors in the collection of data and the manual input or entry of data and has been successfully applied in the retail, logistics and manufacturing industries. Some AIDC technologies, such as barcodes, have found widespread applications in the manufacturing industry within material and tool control, shipping and transportation. [1 – 3] However, the potential uses of RFID within the supply chain have only recently been recognised even though the technology has been available for over 60 years. The increased data capacity and flexible characteristics of Radio Frequency Identification (RFID) technologies have highlighted them as a potential answer for solving these problems and in turn have caused interest from world-class
organisations in their aim to increase visibility [4 – 5]. RFID technologies are expected to offer major savings for an organisation by providing the ability to identify individual items with ease and track them accurately throughout the supply chain, distinguishing their location and movements at all times. However, the substantial investment required for the implementation of an RFID system and the practical challenges and cultural resistance to change that may follow have caused controversy in the true value of the technology. [1][2][6].

It is often thought of as complicated, expensive and time consuming to adopt a new technology project within a company and this is often the reason why many are reluctant to alter their methods. RFID is a technology that is very much tarnished by this assumption and so the real benefits are often overlooked. The scale of implementation and the specific requirements of the system will dictate the investment value required and can vary significantly between cases, so a set cost and benefit assumption for all is impossible. [7] However, the centre for Auto-ID has now established a calculation method for the Return on Investment (ROI) of an implemented RFID system in order to educate companies on the cost benefits associated. [8] Although this may significantly help many companies, the limitations of the calculator often mean that an inaccurate quote is provided. The cost of a tag and the cost of the item to be tagged have limitations set which means that it is often unable to cater for all organisations.

This paper aims to educate and assist organisations with the benefits and limitations of RFID systems within the manufacturing industry, and in particular within SMEs. A method of assessing the cost benefits of an RFID system application has been previously researched by the authors and this case study will be used to support the conclusions made. There is limited research into the adoption of RFID systems within manufacturing SMEs, especially with regards to cost benefits, and so the outcomes of this study aim to assess the true value of this technology within the SME manufacturing field.

2.0 Methodology

The methodology for quantifying a cost benefit analysis outlined in this paper is based on the notion of waste minimisation and lean manufacturing complementing and involving the application of a suitable AIDC technology. Initially, the current manufacturing processes at the SME and the flow of materials and information across the shop floor for each part produced were analysed through a process mapping investigation previously conducted by the author [9]. The aim of the process mapping exercise was to eliminate any operations in the process that are classed as non-value adding. A non-value adding operation is any activity that does not directly add value to the end part or process, or an activity that is classified as a waste. Non-value adding operations should always be attempted to be eliminated from the process, however, sometimes they may be an operation which must be performed for the process to flow but does not directly add value. Such operations cannot be fully eliminated from the process as they are required for the successful completion of the product or service. [10 – 11] The future state manufacturing processes could then be mapped out, taking into account the improvements identified through lean thinking and the implementation of AIDC. Lastly, a cost benefit analysis is conducted in order to weigh the benefits of implementation against the associated costs of implementation.

Once the process mapping exercise was conducted for the current and visualised state of the manufacturing process for an example of each product, a cost saving analysis can be carried out to assess the potential savings that can be made. In order to analyse the savings as accurately as possible, some information and figures were obtained from the company as shown in Tables 1 and 2. The annual sales figures, inventory and tracking data were collected in order to evaluate the cost benefits through improvements.

</tr>
<tr>
<td>Number of Times Physical Tracking is Performed</td>
<td>52</td>
</tr>
<tr>
<td>Time Taken to Complete Physical Tracking</td>
<td>5</td>
</tr>
</tbody>
</table>

The inventory levels kept at the company can be classed as a waste because a significant amount of money is tied up in safety stock. The level of safety stock could be significantly reduced through the implementation of an AIDC system as it can provide 99.92% accuracy through the supply chain [12 – 13]. The potential savings involved for the increased accuracy and in the reduction of inventory through the implementation of an appropriate AIDC system may be calculated using the following equation:

\[
\text{(Total Inventory Value)} \times \text{(Carrying Cost (%))} \times \text{(Safety Cost (%))}
\]

Manual counting times are also classed as a waste as they take a significant amount of time to complete. Manual counting times may be reduced by 80% through the use of an AIDC system [12 – 13] and the savings involved in this reduction of time may be calculated using the following equation:

\[
\text{(Number of times a manual count is carried out)} \times \text{(Time taken to complete a manual count)} \times \text{(Hourly labour cost)} \times 80\%
\]

The process mapping exercise, previously completed by the authors [9] was used to critically analyse the current state of the operations performed in order to establish areas of waste and identify areas that could be improved through the implementation of an AIDC system. The modified state was then visualised based on these improvements for each process and the financial benefits were outlined.

The process efficiency can be drastically increased through the implementation of an AIDC system by the elimination of non-value added operations within the process. In order to calculate the improvements felt in the process efficiency through the implementation of an AIDC system, the cost of the current state process was compared with the cost of the modified state process. This was calculated using the following equation:

\[
\text{(Process duration (h))} \times \text{(Number of parts manufactured per process)} \times \text{(Hourly labour cost)}
\]

Once the process mapping exercise and process improvements were established, an investigation into an appropriate AIDC technology capable of providing these improvements for each process was examined. The suitability of each AIDC technology was examined in order to find the most appropriate system for use at the company. Each technology was considered regarding the areas of equipment size and the feasibility of this equipment with the process at the company, the compatibility of the technology with the products at the company and their surface material, the ability of the technology to function under the operating condition felt by the products manufactured at SVL and also the software requirements for each technology. As all products manufactured at the company are made from metal, an appropriate technology must have the ability to be applied to and perform well on metallic surfaces. The harsh operating conditions such as extreme temperature levels, molten plastics or rubbers, chemicals for cleaning and other general machining that are exhibited in this field of work. A major restraint with for any AIDC system utilised within such a company is the temperature extremities. The technology should also have the ability to be applied to the product without compromising or affecting its performance in any way. These above criteria formed the basis of the investigation into a suitable technology for use within the SME alongside the flexibility of the system itself.
3.0 Feasibility and Application

Through the process mapping investigation previously conducted at the company, it can be seen that the implementation of an AIDC system could significantly reduce the lead times of processes, increase visibility and communication across the shop floor and improve efficiency of the processes. The author has previously identified RFID as the most suitable AIDC technology to be implemented at the company through a feasibility analysis [9] as summarised in Table 3.

<td>− Metal environments may cause poor signal/communication problems in cases</td>
</tr>
</tbody>
</table>

The selection of a suitable AIDC technology also depended on the requirements of the system itself as it is required to be wireless for use on the shop floor. It also must be decided whether or not the technology will be used for the internal tracking of the part only through the manufacturing process or whether the technology must be present throughout the lifespan of the product for future refurbishment. The size and shape of the products manufactured at the SME must be compared with the size of the RFID equipment in order to establish if they are compatible with one another. A comparison of the available RFID tags available was conducted in order to distinguish those of an appropriate size for the products manufactured. Active RFID tags were considered unsuitable due to their size and the presence of an internal power source as they would affect the performance of the product to which they were applied. Passive RFID tags were further investigated as they are much smaller and do not require an internal power supply. Passive RFID tags are available in various shapes and sizes [14] as shown in Figure 1.

![Figure 1 – Types of Low Frequency RFID Tags [14]](image)

The application of an RFID tag onto the parts cannot be external due to the potential risk of damage to the tag itself and also the interference it may cause with the products functionality. The tag must therefore be embedded into the body of the product to protect from damage and allow the product to function properly. The glass type RFID tags...
RFID Systems in Manufacturing SMEs – Benefits and Limitations

were found to be suitable to apply to the products manufactured at the company as they could be embedded into the parts and were small enough to be discreet and not interfere with their manufacturing or performance. The glass tags come in a variety of sizes, ranging from 12mm to 32mm in length which makes them versatile for parts of all sizes with minimum machining for the application. [15]

A major restraint with regards to the implementation of an RFID system at this company is the temperature extremities, as the screw flights are heated to temperatures of a maximum of 200°C during the plasma hardfacing process, which is too high for the glass tags to handle and would cause them to be irreparably damaged. However, only the screw flights are subjected to this process and so the tag may be placed in a different area of the part to avoid damage through the hardfacing process. If the RFID system is required to be present on the product throughout its lifecycle, in the event of refurbishment being required, then it would be subjected to operating temperatures ranging between 110°C and 320°C. However, there are areas of each product that are not subjected to these extreme temperatures which would only experience temperatures up to a maximum of 90°C and the tags would therefore have to be applied to the area of the product that is exposed to the least heat. For example, Figure 2 shows some screws and barrels manufactured at the company, the drive section of the screw and the section of the barrel before the hopper slot would be the places when temperatures were lowest at all times and so the tags may be embedded here to avoid damage. The RFID system would also be expected to withstand certain levels of oil, grease and dirt along with levels of damage that could occur throughout the manufacturing operations that the product would be exposed to. The application of an embedded glass tag with an adhesive resin for protection has the ability to withstand such conditions. The fact that the tag is embedded within the part would avoid levels of damage through machining and the adhesive resin used with the glass tag would provide a waterproof and protective coating that would not allow grease, dirt or liquids to reach it.

![Figure 2 – Barrels (left) and Screws (right) manufactured at the SME](image)

RFID technologies are known to have some limitations when used with metallic objects as metal interference can significantly reduce the reading range of the tag and also may cause loss of information through interference. Low frequency (LF) glass type RFID tags were found to be the most appropriate solution for this problem as they may be easily embedded and set in place through the use of an adhesive resin, which would provide protection for the tag from grease and oil and also provide a barrier layer between the tag and the metal surface which would allow for the data to be read without any interference.

4.0 **Cost Benefit Analysis**

One of the main barriers to the successful implementation of an RFID system, especially within an SME, is cost. Due to the fact that the current level of research into the successful implementation of RFID within SMEs is limited and the level of education in SMEs with regards to RFID is inadequate; there are many perceptions that the cost of implementation is far greater than the benefits. [7, 16-17] This is also burdened by other factors; such as the implementation of a new technology within a company requires education, support from all workers, sufficient funding and can also be time consuming. RFID technologies are expected to provide major savings for an organisation by providing the ability to identify individual items with ease and track them accurately throughout the supply chain, distinguishing their location and movements at all times. However, the substantial investment required for the implementation of an RFID system and the practical challenges and cultural resistance to change that may follow have caused controversy in the true value of the technology. [16]
There are currently no standard methods known to calculate the ROI for the implementation of an RFID system as it will vary greatly for each company. In order to establish the cost benefits of the implementation of an RFID system within the company, a number of simple calculations can be carried out. The savings that can be observed through the implementation of an RFID system were outlined previously through equations (1), (2) and (3) and the results of these calculations are as follows.

The level of safety stock could be significantly reduced through the implementation of an AIDC system within the company. Using the data collected from the company, Table 2, the estimated savings that can be gained from the reduction of inventory levels through the implementation of such a system are as follows:

\[
\text{Savings} = (\text{Total Inventory Value}) \times (\text{Carrying Cost} \%) \times (\text{Safety Cost} \%)
\]

\[
= (£130,000) \times (10\%) \times (50\%)
\]

\[
= £6,500
\]

The cost of manual counting and tracking times can be reduced by 80% through the implementation of an AIDC system. The manual tracking of the jobs across the shop floor was completed on a weekly basis and took 5 hours in total to complete, including the manual input of the results. Using the data seen in table 2, the estimated savings that can be seen through the reduction in the costs of manual tracking can be seen to be:

\[
\text{Savings} = (\text{No. of counts}) \times (\text{Time taken per count}) \times (\text{Hourly labour cost}) \times (80\%)
\]

\[
= (52) \times (5) \times (10) \times (80\%)
\]

\[
= £2,080
\]

The process efficiency may also be increased through the implementation of an AIDC system through the improvements stated in the process mapping exercise outlined. In order to calculate the predicted saving improvements in the process efficiency through the implementation of an AIDC system, the cost of the current state process must be compared with the cost of the modified state process, which is calculated using equation (3). The elimination of the non-value added processes allowed a time saving to be measured for each process which was used alongside the data from tables 1 and 2. The amount of hours saved for each process were then used to calculate the cost savings per process. The annual cost savings could then be calculated by multiplying the number of processes per year as seen in table 4.

**Table 4 – Cost Benefits for Each Process**

<table>
<thead>
<tr>
<th>Process</th>
<th>Hours saved per process</th>
<th>Cost savings per process (£)</th>
<th>Cost savings per year (£)</th>
</tr>
</thead>
<tbody>
<tr>

<td>Barrel Refurbishment</td>
<td>4</td>
<td>(4) x (1) x (10) = 40</td>
<td>(40) x (50) = 2,000</td>
</tr>
<tr>
<td><strong>TOTAL</strong></td>
<td></td>
<td></td>
<td><strong>£58,625</strong></td>
</tr>
</tbody>
</table>

The improvements in the process efficiency and transportation times in particular can be identified through the use of process activity mapping and flow across the shop in order to add value to the operations and also savings in the reduction of safety stock levels and manual part counting can also be identified. The total annual saving that
were calculated for the company across each of these areas through the implementation of an RFID system and the improvements in the shop floor layout are outlined in Table 5.

Table 5 – Annual Savings

<table>
<thead>
<tr>
<th>Savings</th>
<th>Amount (£)</th>

</tr>
<tr>
<td>Process Efficiency Savings</td>
<td>£58,625</td>
</tr>
<tr>
<td><strong>Total Annual Savings</strong></td>
<td><strong>£67,205</strong></td>
</tr>
</tbody>
</table>

The process efficiency savings were calculated through the improvements to the operations in each process and the shop floor layout across all products produced annually. In total, the recommended alterations and implementation of an integrated RFID system has the ability to save the company an estimated £67,205 per year.

The cost of the RFID tags themselves has been previously identified as a major disadvantage of the technology [16 – 17] and was therefore investigated with respect to the requirements at the SME. The glass tags that were identified as the most appropriate technology for the application of an AIDC technology within a metal part that is exposed to harsh working conditions were found to range from £1.50 to £2.80 per tag dependant on the size required. The cost of these tags was found to be negligible with respect to the value of the products manufacture at the company. The handheld RFID reader devices were found to range from less than £500 up to over £2000 pounds for a pair including a power cradle [18 – 19]. The appropriate reader system required would need further investigation and again depends upon the level of interference felt from the metal environment, the reading distance required and the facilities required from the device. The installation and integration costs of an RFID system were found to range between £23,000 and £25,000.

The investment necessary for the implementation of an RFID system is highly dependant on the requirements of a company and the hardware chosen. The implementation costs for the SME were initially established as summarised in Table 6.

Table 6 – Implementation Costs

<table>
<thead>
<tr>
<th>System Requirements</th>
<th>Associated costs</th>
<th>Investment Required (£)</th>

</thead>
<tbody>
<tr>
<td>Tags - £2.00 Each</td>
<td>580 required for ‘new sales’</td>
<td>£1160 (per year)</td>
</tr>
<tr>
<td></td>
<td>(580) x (2) = 1160</td>
<td></td>
</tr>
<tr>
<td>Extra Labour Required for Tagging</td>
<td>30 minutes allowance for each tag application</td>
<td>£2900 (per year)</td>
</tr>
<tr>
<td></td>
<td>(Time taken for each tag (hrs)) x (hourly labour (£)) x (No of tags)</td>
<td></td>
</tr>
<tr>
<td></td>
<td>(0.5) x (10) x (580) = 2900</td>
<td></td>
</tr>
<tr>
<td>Hand held Readers</td>
<td>(£2000 per pair) x (6 required)</td>
<td>£12000 (one purchase)</td>
</tr>
<tr>
<td></td>
<td>(2000) x (6) = 12000</td>
<td></td>
</tr>
<tr>
<td>Software and installation costs</td>
<td>£25000 max</td>
<td>£25000 (one purchase)</td>
</tr>
<tr>
<td><strong>Total Initial investment required</strong></td>
<td></td>
<td><strong>£41,060</strong></td>
</tr>
</tbody>
</table>

The initial investment required for the implementation of a suitable RFID system has been calculated as £41,060 with an additional cost of £4,060 per year to tag each new product manufactured. The ROI of the RFID system could therefore be calculated by dividing the cost benefits of the system with the investment required to implement the system.
ROI = (Cost benefits of system (£)) / (System implementation costs (£))

= (67,205) / (41,060)

= 163.68%

The ROI for the implementation of an RFID system within this company was found to be 163.68% which means that the payback period is about 8 months.

5.0 SUMMARY

The major barriers for the successful implementation of an AIDC system within a company are found to be: the lack of basic IT infrastructure, the reluctance to invest in new technologies due to lack of education and knowledge in the subject area and cultural resistance to change. A major issue for the implementation of an AIDC system within an SME is the requirement of a computerised infrastructure as a prerequisite as this is associated with high costs and vast amounts of training. [20 – 22]

The accurate traceability of products throughout the manufacturing process can improve the efficiency of a process, the accuracy of the information available and improve the lead time of the product. The traceability of parts may be improved through the implementation of an RFID system with components that are capable of withstanding the conditions of the part. Passive LF glass type RFID tags were identified as a viable solution as they may be embedded into the metallic parts produced at this company and can withstand all conditions felt through the products lifecycle.

The cost benefit analysis for the SME through the implementation of an RFID system and the modification of the shop floor plan was found to provide a saving of £67,205 annually with a payback period of around 8 months. Significant cost savings are found through the implementation of an RFID system based on the reduction of safety stock, the elimination of manual job tracking and the reduction of the manual input and written data throughout the process. The modification of the shop layout better facilitated the use of an RFID system as well as improved the efficiency of the process by providing increased visibility and a large reduction in transportation times.

ACKNOWLEDGEMENTS

The author would like to thank all of the employees at the SME for their support throughout this case study.

ABSTRACT

The ongoing development of technologies has in recent years lead to a significant increase in the available technical equipment of private as well as commercial buildings, which makes a computerized monitoring and control of mechanical, electrical and energy systems, possible. Known as building automation products and systems that lead to a significant improvement of individual life, safety and working conditions are all combined in this term. With the introduction of building automation techniques like function cycles in systems automatically enforced according to preset parameters make the servicing and monitoring easier. However, products from different manufacturers have to work in any combination with each other, this is very beneficial for customers, but from the perspective of manufacturers and system integrators it poses major problems. The reason for this is the heterogeneity of the products and the difficulty to implement interoperability. During the life cycle of a building it comes repeatedly to changes in the buildings technology for example. This begins with the planning phase and goes on to the commissioning and the continued use of buildings, the space requirements change, leading to a new configuration of the initial automation and manual intervention within the different levels of communication is necessary. Such changes are particularly burdensome especially when a large number of different components from different systems are affected, resulting in a considerable requirement of resources due to the multiple entry of data, inconsistency and incomplete documentation because of knowledge islands. Thus even small changes evolve to complex reconfigurations. The following article deals with a software framework that outlines this problem and allows major simplifications in the administration and modification of complex spatial configurations in the building automation. It shows how digital 2D building plans can be evaluated so that geometric data contained on automation components are automatically read-out so that they can be managed with total control from the central framework.

1. INTRODUCTION

With the construction of a new building, e.g. a family home, various sections of the building automation systems are installed and in operation. Despite standardizations on the communication level, by BACnet or LON, this is currently done with a relatively high cost, as these heterogeneous systems / devices must communicate with each other. On the side of the system integrators (craft industry) it takes know-how and considerable time to implement the necessary control functions. Subsequent extensions of automation components, such as the integration of new sensors or actuators, nowadays often require special solutions, in which problem-specific extensions are programmed, most of the time other applications besides the original are not usable. The user has to use decentralized control elements to those components with isolated features, for this often special skills are required, such as in the management of the heating system. The consequences of this are that these media and the process breaks, spread over the entire life cycle of automation systems in buildings starting from planning, through its commissioning, management and maintenance, through to its disposal (cp. figure 1).

Another challenge in the field of energy-efficient building is total integration of several automation systems. To do this they need to adapt to their environment by using the "environmental job," for example, air conditioning, lighting or energy production, use and freely available resources. System integrators will need an in-depth knowledge, ranging from components and wiring in the physical level to domain-specific functions and the abstract connection specific functions of various trades on the logical level. For this reason, new methods are needed; a simplified, manageable and cross-system building and configuration that allows easy small projects management by small and medium-sized systems integrators.
The here outlined problems have been met in the past with various approaches to a largely automated support of the life cycle of building. There has already been put some effort in the standardization of the data protocol to ensure that devices from different manufacturers can be combined, examples for this are BACnet and LON. However, these efforts stay behind their expectations because of various problems (see [1] [2]).

In the interest of geometric and functional planning of the building (GA) in the engineering phase up to this date various software tools available. For the geometric design of a plant 2D or 3D CAD programs can be used. Most are AutoCAD based and cover all domains of the building, such as ventilation, heating, lighting, access control, photovoltaics, such as "Rocade" of Mensch und Maschine AG [3]. In addition, there is specific software such as "Elaplan" of ElektraSoft [4], "Vaillant WinSoft" of the company Vaillant [5] or "Simatic Automation Designer" by Siemens [6] etc. offers additional features for building systems, such as inventory management, cable laying and generating schedules of images for monitoring and control. They work on CAD-based or have interfaces to CAD systems and standard calculation programs with import/export functions. However, these systems are confined to the data generation and management, and generally have no intelligent combination of data types. Therefore they do not allow for seamless transfer of geographic positioning of the components and cover only the planning stage.

The monitoring and control of a facility is realized with so-called S.C.A.D.A. * tools, covering a wide range of programs for monitoring and control of a GA facility. Some S.C.A.D.A. systems already provide interfaces to CAD systems. "WizCAD" for example converts with the module "Wizcon Supervisor" [7] AutoCAD plans to Wizcon S.C.A.D.A. -specific files. In "PVSS II" [8] CAD plans are converted to XML-based system PVSS pictures. These are application-specific interfaces, which are usually based on proprietary mechanisms. Additional extensions or linkages with other systems, are if the exist at all, limited.

In the area of maintenance and alteration within the Building Automation, special software tools from the realm of facility-/building management is used. Such software evaluates the disruptions caused by coupling with management/building automation, oversees operations for routine preventive measures and has interfaces to software management products. Thus, e.g. the staff at alarm cases can assess the priority for messages and alert the fire service or the service disruption. The system can also trigger the ordering process, when not enough parts are available. A major disadvantage is that there are elaborate procedures for the configuration and implementation of such mechanisms, because of the data exchange of the system with other applications via proprietary interfaces.

Overall, it is observed that isolated solutions for open, cross-system communication and functionality of the systems with automated setup, configuration, modification and coordination of building systems, are currently available only in the research environment. For example, in the project "VIMP" at the University of the Bundeswehr

* S.C.A.D.A.: Supervisory Control and Data Acquisition
Munich with "IMOS home" a tool for planning, commissioning, visualization and operation of an intelligent houses is developed. The linkage of planning with the S.C.A.D.A. functionality is "IMOS" in an interactive graphical user interface with 2D virtual realistic 3D objects is realized [9] [10]. However, this is a concept for systems with a manageable number of components. For the private sphere of life and industrial applications with a large number of nodes, it is not suitable. Furthermore, it is questionable to what extent additional specialist knowledge on the part of the system integrators due to the 3D visualization is necessary. The same applies to that of program InnoNet sponsored project AUTEG, which is trying to design an automated process of building a complex investment [11].

2. REQUIREMENTS OF THE FRAMEWORK

The framework has the ambition of a generic approach to the lifecycle management of automation systems. Therefore, its development has been made in the following two main applications, as well as numerous scenarios of building automation and energy management, which later led to the validation of the results:

• **Model Transformation to configure third-party systems:** The framework is an interpretation of 2D drawings and the generation of object models in formats allows any target, so that the drawings implicit information decrypted by third-party systems are used. This will allow these 2D planning documents as a basis for other configuration systems that are reducing the time and resources for the manual input of data costs. Furthermore, this approach allows for configurable model transformation consistent, redundancy-free and full harmonization of data from different life stages of automation systems with the condition that any changes only in the 2D models are implemented.

• **Generic monitoring and control of heterogeneous automation systems:** An Internet user is the one all interpreted data based on a generic model and visualize rudimentary functions to interact with users. But it should be possible to use data via pre-configured WebServices on this surface. Through this way it will be possible to monitor and control actions to heterogeneous types of automation systems on generic basis and thus an integration of these systems at the level of user interaction.

Based on these cases and scenarios, the functional, technical and management requirements are derived. The main concern of a configuration based adaptation of the framework for different application domains without the need to implement complex functions as well as on the intuitive and user-friendly, respectively efficient interaction with the end user.

2. CONCEPT OF THE FRAMEWORK

Based on the above-described problem for small and medium-sized enterprises (SMÉ), a suitable software framework of FZI Forschungszentrum Informatic supports the lifecycle of buildings fully. It simplifies the management and modification of complex spatial configurations, by using digital 2D AutoCAD building plans (.DXF or .dwg) geometric data contained on automation components in terms of their control are automatically interpreted. The information obtained represents the spatial configuration of the overall automation in a building and can be on the framework-specific function possibilities using database, XML or Web service interfaces. In this way, it is possible for any PC-based or embedded control units to expand, resulting in an automatic transfer of these configurations. In addition, the framework ensures a uniform spatial configuration of automation systems for visualization and rudimentary communication with the control units via Web Services. An open technologies (Java, Eclipse, GEF etc.) based viewer interprets this data on demand in formation and services easy to control, for example, all energy-related components from a 2D drawing planning to extract and visualize. For the users of the framework is thus the ability to communicate information about such components (such as current performance of the photovoltaic component, total electricity consumption, the state of window sensor) is retrieved.

2.1. COMPONENTS OF THE FRAMEWORK

The framework consists of five core components that are either used together or individually in different applications in the field of information management automation and energy systems. Below the individual modules are briefly described (cp. figure 2):

The AutoCAD Interface provides an interface to export 2D AutoCAD drawings into a specially adapted to the requirements of the Framework XML data format. The exported, geometric components can be configured so that
only the necessary information for the subsequent rule interpretation is available. It can also include data from other systems within the framework over the XML interface if the adapters are available.

The Schema Editor as an Eclipse RCP application allows the creation of information objects for the monitoring and control of building automation, without an implementation. For each object properties of different types of data and references to Web services, rules for the interpretation of 2D drawings and the SVG graphical metaphers can be added.

For rule interpretation or semantic enrichment of the CAD system exported data, the Rule Engine is used. The complexity of the generic approach for the adoption of spatial configurations from differently structured CAD drawing data as well as the requirement for transparent and user-friendly configuration make the use of exciting rule technologies impossible. The adjustment flexibility and the clarity of the interpretation of logic can only be customized with a scripting language. The interpretation process is thus dependent on the structure of each the evaluated data from each drawing. In addition, this script is characterized by a dynamic language typing, thus an additional definition of a schema with data type formats to interpret the underlying XML data is nor required.

The backend database connectivity and Trans Pain ter Framework manages all interpreted data, creates an abstraction layer between the database and object-oriented programming language used and adjusts the communication with the frontend. To minimize the effort on the client side, "Painter" classes are provided by the server. A Painter class provides a Java class that contains the instructions for drawing an object. It implements a special interface, which the client (Web browser) draws to instances of this class directly to the object to a Java2D Graphics instance. By keeping the technology within the framework the web browser barely needs libraries to display and a very low volume of data transfer via the Internet occurs.

A central element of the Framework is the front-end component Front end 2D represent ation Java2D appl et, which allows the visual presentation. The presentation is provided through Remote Method Invocation (RMI) by the backend. In order for the Java2D appl et to load as quickly as possible, it is the Trans-Framework Painter from the backend. In addition, large amounts of data are visualized as powerful information through dynamic loading.

For the presentation of the logical topology of the automation and energy systems and for the attributes and WebService various components the Frontend GWT component is used.

Using a Web services interface allows data from third-party systems to the generic web interface from the Framework and control instructions to third-party systems using Web services. From a WSDL file selected configuration of the Web is with the object model of the atomisation / energy system linked so that the correct Web services on the surface of the context are represented.

Figure 2: Framework Architecture
2.2. DATA MODEL OF THE FRAMEWORKS

The heart of the framework described here is the generic data model, which is a configuration instead of a deployment of the types of information objects. The data model includes three main groups (see figure 3):

- the domain model for information about the environment in the framework of the ECS
- the logical model as an instance of the domain model with concrete objects (nodes) and their attributes
- graphic model for the visual representation of the objects

The domain model serves as a meta model to types of real or abstract objects. Here the types of attributes, Web services references and interpret rules are defined. Optional is a relationship with a view (form) in the graphic model, to be able to define how objects of each type are presented. For example, a type "fan" with an assigned representation, as well as an abstract type "channel" without assigned representation is possible. The logical model is, however, specific instances in the domain model types. Each object (node) is therefore assigned to its type and its attribute values. Objects, attributes and types of objects are on clearly identified through their names. The graphical model is separated from the logical model and provides topological structures and abstract objects. Not all of these objects have a visual representation. There are also visual objects without logical or topological mapping function, such as building data. Each node graphic is optional, and therefore an object of the logical model. Thus, even indirectly, the presentation of the object is defined. Alternatively, the presentation can also be directly assigned, for example, to a building or channel data lines.

![Figure 3: generic data model](image)

4. APPLICATION EXPERIENCE

The continuous support for the lifecycle process of a building in the developed software framework has been applied in two different fields of automation applications. It showed up in the framework through a cooperation with a large manufacturer of cleanroom systems, that in all phases of the plant lifecycle data produced consistently and without media breaks can be managed. In addition, a so-called energy-control system on the basis of the framework in collaboration with a maker of monitoring and control software for renewable energy is created. This system transferred the configuration from a single 2D drawing file systems for photovoltaic, wind and hydro power plants and offers a generic way to visualize the individual components and to control it via the Web (cp. figure 5).
The complex problem of cleanroom control, as one of the two applications, it is clear from the large number of fans (known as Fan Filter Units), typically 500 to 25,000 units, which are depending on the associated space expiring production in different work arrangements air with reduced proportions of particles blow. The monitoring and control systems regulate the smooth and energy-efficient operation of the whole system, which is a common communication and interaction with other building automation systems. For example, the event of a fire hazard, the corresponding signals from the fire protection system are received and interpreted accordingly, so that geographically nearby fan to prevent the fire from spreading. The planning of such plants will be conducted with 2D drawing programs, where the modelling of components and compounds in developing specific guidelines set primitives. In the current industrial practice, this information may be for the installation and repair not automatically be accepted. The physical link between the components must be manually matched with the planned configuration and should be examined for compliance. For the configuration of the interaction with other building automation systems, the spatial data in turn has to be done by hand (cp. figure 4).

A special adaptation framework, the expectation for continuity of data along the software system is fully met. All relevant components and compounds were from 2D AutoCAD drawings with preconfigured interpreting scripts provided. So were the object models for individual software systems throughout the plant lifecycle completely automates generate. A redundant manual data entry for the commissioning, monitoring and control system was therefore completely avoided. The examples are configured clean rooms were available in any internet visualized and necessary control functions via Web services are running.

![Image of graphical user interface](image.png)

Figure 4: The graphical user interface of the domain configuration of the clean rooms control system

The second scope, concentrates on the advantages of model transformations for the configuration of monitoring systems and the benefits of a harmonized view of heterogeneous systems with data coming to the domain of energy from renewable sources plants. Optimum energy yields from such investments are created in energy parks, with the operators of electricity from different energy sources, such as photovoltaics, wind power and hydropower combined. In order for them to act quickly will be a simultaneous viewing of relevant information from all sub-systems is essential. The heterogeneity of the systems and types of plants makes an integration of the software systems virtually impossible. Furthermore, the Energy Park for the whole configuration information is only created manually or with complex direct interfaces with proprietary systems, so that future changes opaque and are difficult to be carried out.

The framework based Energy Control System (ECS) has a solution to the demonstrated problem. The planning of the energy park was seen as 2D models drawing, resulting in the configuration data for all relevant software systems of the plant life along with the corresponding interpretation script. As an example in figure 5 spatial information

- for a Google Maps web realized overview,
- for a management system for asset master data and
- for a monitoring and control system for photovoltaic installations is demonstrated.
All existing data in the system could be visualized on a web-based interface. Through this for the first time the data of a wind and hydro power plant without additional implementations (only configuration) in a harmonized view are presented side by side.

Figure 5: Application examples in the domains of renewable energy systems (schematic representation)

4. SUMMARY AND OUTLOOK

Building automation is becoming increasingly important both in the industrial and in the private sector, for example, by providing flexibility in the support of old / disabled people or contributing to everyday comforts. But also because of the multitude of possibilities for energy-efficient buildings in the operation of private and business buildings the importance of such systems is steadily increasing. Commissioning or changes in the buildings require the transfer of spatial configuration of automation components in several heterogeneous tools, often with a huge manual effort and constantly repeating routine activities. With this present contribution, the concept and application experiences of the FZI Forschungszentrum Informatik Karlsruhe (Germany) a newly developed software framework has been presented. This allows the consistent and lifecycle-oriented management of complex spatial configurations of automation systems in buildings. It also allows small and medium-sized components, system vendors and system integrators to offer modules that help to easily integrate powerful and individual IT solutions along the building automation life cycle.

The objective of future development of the framework, is to put focus on the energy sector. It is planned to use a user-specific configuration and modeling of the energy supply, in various detail and quality levels, evaluations of energy depending on the usage behavior. For this appropriate presentation and analysis options have to be available, based on a unique space-time event-based relationship. On one hand users get an accurate overview of their specific energy consumption behavior in the various phases of use, such as holidays, work week or weekend and are thus optimized in terms of energy-aware behavior. On the other hand, the automated derivation of individual actions and identification of weaknesses in the configuration of supply and provision of user behavior, can result in significant energy savings.

ABSTRACT

In the present era of globalization, SMEs need additional support to stimulate forthcoming business opportunity. It totally depends on the best strategies to improve quality performance and reduce the defect rate of manufactured products. This improvement could be achieved through the practices of SPC to control, monitor and managing process specifically at production site. SPC can be conducted as simple as analyzing data and plotting charts. This paper highlights the outcomes of an effort to develop the SPC computer based system intentionally to perform simple statistical analysis as well as to manage the quality data processes. The system named as SMEs-SPC (Small and Medium Enterprises - Statistical Process Control), has tended to focus on particular data sets, simple statistical operations and users group. This paper is a continuation study which focused on the development and application of SPC system in a case study company. The results showed that the SMEs-SPC applications are applicable to all types of processes, machines and parameters to store the information, data and subsequently generate the graph. The utilization of this system may help organization to train and educate employees on SPC application, which could become one of the strategies to improve the quality management tool. The value of this study would be particularly useful to SME companies that are contemplating the adoption of advance manufacturing technology.

1. INTRODUCTION

According to O’Regan and Ghobadian [1], strategy is commonly to have a few different numbers of meanings. A definition by McDonald [2], strategy encompassed some elements such as focus on long-term performance of the organization, determine the activities of the business that parallel to the environment toward stimulate maximum opportunities and propose the organization’s activities based on resources available. Indeed, deploying strategy enable the company to expand the business as efficiently as possible towards the performance improvement. Samat et al. [3] believe most organizations in Malaysia have started to concern about quality as an essential part of their strategies in order to meet challenges and improve their positions in the marketplace.

Nowadays, Statistical Process Control (SPC) method has been implemented with success in many large organizations but there is still less efficiently used in smaller organizations specifically in Malaysian Small and Medium Enterprises (SMEs) manufacturing companies. However, Antony et al. [4] believe due to increasing of high capable business and competition in domestic and global environment, large organizations mostly depend on SMEs to deliver higher quality of products at lower cost. Thus, SPC has evolved into a business strategy in many large organizations. Therefore, SMEs has left no choice other than to consider the introduction of SPC methods at their production site.

This paper aimed to report on the new dynamic system (as a tool) for manufacturers in SMEs in order to perform simple statistical analysis and manage quality data processes. The system named as SMEs-SPC (Small and Medium Enterprises - Statistical Process Control), has tended to focus on particular data sets, simple statistical operations and users group. In addition, this study attempts to assist SMEs to make quick corrective action or instant decision making of quality problem, as well as encourage production workers from operator level to adapt with the SPC computer based efficiently rather than traditional SPC or manual techniques. Dangayach and Deshmukh [5] contend that, the effort to reduce operating costs and improved manufacturing efficiency has realized some
manufacturing organizations to further experience on direct and indirect Advanced Manufacturing Technology (AMT), or can be described as group of computer based technologies, including Computer Aided SPC (CASPC) or SPC computer based applications. Therefore, SMEs-SPC system described in this paper will contribute and offer some further advantages.

2. THE NEED FOR SPC IN SMEs

Generally, the long-term goals for SMEs are to persist in business competitiveness, survive, raise and make profits. One of the fundamental ways to achieve this goal, SMEs are urged and must reduce several items of failure costs or waste items including rework, scrap, warranty claims, product recall and others. In their studies, Ab. Rahman et al. [6] believe SMEs plays an important role in gaining competitive advantage. According to them, there are two fundamental reasons to use SPC in SMEs; SPC is necessary because large companies will require high quality product at minimum possible costs and it is the survival necessity in this high competitive business environment. According to Xie and Goh [7], manufacturing sectors have benefited from the implementation of SPC tools/methods to lead in decision-making process. In essence, control charts and process capability utilized through the implementation of SPC are proposed to identify and enhance the process performance. This fact also supported by Surak [8], suggested that there are several resources to implement SPC, such as software selection, control chart, histogram and capability indices to identify the improvement items in process. In addition, control chart is useful because it able to distinguish between assignable and common causes of variation in the process [9], while process capability purposely to measure the actual output of a process and then compare the capability to the specifications given for the process or product involved [10; 11]. Alternatively, process capability consists of three primary techniques including histogram or probability plots, control chart, and designed experiments [9].

According to Antony et al. [4], the utilization of CASPC has received more attention by many organizations. For example, many companies preferred to use spread sheet software to develop control charts. However, many manufacturing organizations still remain on using traditional SPC or manual practices (e.g. paper-based control charts). Consequently, traditional SPC focused on particular limitations where only little quality faults are detectable, time-consuming and burdensome. Moreover, they do not really understand the purpose of quality data collection and there is no systematic way for them to efficiently manage and organize quality data processes. Furthermore, Hofmann et al. [12] stated that a problem regards to statistical software in company is not portable and multiple users since the system developed for one specific computing. From researchers’ point of view, quality data or information could be shared via online or server application to perform data analysis, as well as to provide reports in the standardized formats. The researchers have considered this limitation in developing the system.

From the previous study [6], the researchers have typically identified the problems of using SPC and the barriers that may prevent the SMEs in Malaysia from adopting SPC software or system effectively. The results revealed that some problems (found in the preliminary study), for example lack of efficiency of quality data management, calculation errors, inconsistent format, limited access in data collection, complicated specifically for operators and the system or SPC software is very costly, while some barriers are also exist due to the lack of awareness to the importance of SPC applications. These facts indicate that the implementation of SPC is believed to be appeared at a moderate stage in Malaysian SMEs. Lack of top management support, high cost of technology and lack of skill workers are also the barriers to SPC implementation. Therefore, this paper will focus on the development of SPC system computer-based which the system offers at lower cost, simple statistical operations, ease-of-use for production levels, extensible to access data at flexible times; reduce time to input and retrieval historical data, prevent errors in calculation, trigger out-of-control data automatically, avoid late/delay information on out-of-control event in production, provides interesting features as well as standardized report and consistent format. Therefore, in this research, with the co-operation between government, industry and university, it outlines the development of SPC computer-based system for conducting statistical analysis on production processes as well as, assists the company operations performances.

3. RESEARCH METHOD

A case study can be used when attempting to understand complex organisation behaviours. The case study is especially appropriate when trying to answer the “how” and “why” questions in exploration of the research problems. The case study typically involves a small number of cases which are not necessarily represented of the larger population. Data collection for case studies may come from various sources such as interviews, company documents, archival records, observation and physical artifacts. Moreover, this method need not always include
Improving Process Performance through SMEs-SPC

direct and detailed examinations as a source of evidence as required in qualitative research [13]. To meet the aim and objective, primary case studies were conducted at ten manufacturing companies (SMEs) located around Selangor (Klang Valley). In this period of study, data and information were gathered from various sources such as interviews, survey (questionnaires) and observation. The type of companies involved includes automotive, electronics, medical disposal devices, computer components, plastics and chemicals. Most of the engineers or managers involved were from production or quality department, since this study focused on the production site. In general, this study is concerning on company background, perception and level of SPC practices, types and characteristics of SPC software used, advantages, barriers, suggestions and, seeking for potential companies to develop/use the SPC system.

The study is enhanced and involved case study investigation and collaboration with the automotive company, by focusing on process characteristics, collection of existing quality data processes, process control sheets (paper-based control charts) and users group involved in the process. The study encompassed design and development of SPC system based on process control sheets and control process plan provided by the company, as well as consulted by company requirements and academician suggestions. However, this paper is only focus on the first phase development of SPC system which involved initial trial or pre-testing of the SPC application based on existing data provided by the company. Future study will focus on the development of online SMEs-SPC system based on local area network that provided the means to share software and data information in solving quality problems at the case study company, and other SME types of business/operation that compatible with the SMEs-SPC system.

4. RESULT AND DISCUSSION

The studies’ outcomes are summarized based on the simple SMEs-SPC application, developed for a case study company, named by company A which is simple and not too complex as compared to other commercial statistical software. Note that, the system may be used effectively by anyone who does not have a strong background in statistics specifically for operators at process/production sites. In short, SMEs-SPC system is integrated by client server database that refers to MySQL (Structured Query Language) with back-end relational user interface developed in Microsoft Visual Basic. All tools or object models of visual basic are used to access SQL server. Based on stored data in database, visual basic is responsible to compute or performing statistical calculations. User interface provides the user with intuitive graphical tool to analyses data through control charts and histogram. According to this, the MySQL is supported by admin software to manage a whole MySQL server such as browse and drop databases, create tables, views, rename, export and import databases and others as shown in Figure 1. On the other hand, developing SPC system through a main server application allows many users to use the same software, share the same data sets and sharing knowledge about capabilities, limits, graphs and out of control event. For example, these three contexts in company A encompassed production to quality control (QC) to top management in order to inform and make instant decision making of quality problem in process site. Figure 1 shows the schematic diagram designed for company A which involved MySQL server database and admin application that assigned to manage database as well as directly linked to the user workstations. Currently data quality processes or variable data is not only to monitor the variation of process, thus it is used for the presentation of standard reports and graphs. It can facilitate end users to compare process stability performance across different time, values and process.

![Figure 1: Schematic diagrams for SMEs-SPC connection system](image-url)
All users must confirm their identification with MySQL admin to enter onto this system by login the username, passwords and company name. The results will pass directly to admin before user allowable to enter the SPC system. There are some privileges provided by this system such as multiple users or easy to access and enable to use at flexible time around local company; enable to trace the user who delete or edit data values; enable to protect confidential data by security password given. Detail of how it works or data flow diagram is shown in Figure 3. This section is responsible for generate stored data. MySQL admin is typically consisting of six separated tables in order to differentiate data values and add variable information, as well as to assist in computing statistical operations. SPC data processing takes the user’s information or parameters to be applied such as variables used, types of control chart to perform, subgroup size, time and date entered in data entry as well as user define control limits to manage according to the table/report respectively.

![Figure 2: Data flow diagram](image)

In this section, SPC data processing is responsible to organize the stored data and finally passes these results into SPC information system for graph generation and process capability underlying of statistical formula. Thus, development of this system tended to use more graphical common button that offers interesting key features rather than spread sheet software. It is easier to allow user to control the button and generate calculation, graph and report by following simple instructions. For example, users enable to define their own control limit and select control chart rules suit to the company requirement. In some cases, the system is facilitated with code color either red or yellow to trigger out of control event. Feedback action via email can be executed to inform this event. This part becomes very important to inform real time problem occurs in process or production.

From the researcher’s studies, the calculation or SPC operations required by SMEs companies are basic enough such control charts (X bar-R charts and X bar-S charts), histogram and process capability indices. One important issue is regarding on calculation accuracy, as compared to established or commercial statistical SPC software/system, is that the statisticians have verified its calculations. To address the issue, the calculation results in SMEs-SPC system were checked against Excel (programmed of SPC formula) and SPSS. Finally, compare the existing process control sheet or data provided by company A to verify their accuracy with this system. The only case in which the results did not agree was in the calculation of normal curve as well as it shapes and varies slightly.
between established packages such as SPSS and Excel. SMEs-SPC system used the formula of normal curve proposed by Smith [14].

In the context of this system, it development is not intended to be a replacement for the complete and complex statistical operations offered by other/current commercial software packages, which currently used by industry (such as Minitab, SPC Excel and Microsoft Excel). Another important feature, this system is not based on spread sheet or in tabular form and also does not require function or syntax name for conducting statistical calculation as compared to the existing commercial software. Finally, the instruction given in 'help' button is user friendly and easy to understand by all levels. Other important features, the results of SPC data processing by SQL queries are placed into a result table with a standard format and label, to enable processing by any components of the system. For example, the result table stored the main process folder, sample size and subgroup size, and running data including specifications, target, data values and others (e.g. see Figure 3). Another enhancement in this system is the possibility to create final reports that consists of image files and text results. In any case, the possibility of creating presentation-quality reports via SMEs-SPC system is an appealing one.

![Figure 3: Running data](image)

4.1 APPLICATION AND USER INTERFACE FEATURES IN SMEs-SPC SYSTEM

In order for SMEs-SPC to be useable specifically by production levels, graphic interface provided in this system is one of the advantages that attract the users’ interest in performing systematic data calculations. At initial method of application, users should input raw data or quality data process into the system to perform statistical analysis quickly and easily. Then the result displays either as text or in image form. These results should be able to identify whether the variation occurs in control or out of control. The system also performs capabilities calculations to determine the capable of process.

![Figure 4: Login information](image)  ![Figure 5: SMEs-SPC system introduction](image)

In addition, SMEs-SPC is aimed to suggest improvement of some problems as found in the preliminary study. Specifically to enhance the efficiency of data quality management, encourage operators or productions level to handle SPC based on computer rather than traditional SPC (paper-based control charts or manual calculation) and
The following figures address interfaces features available to the user and it is expressed in each interface. A beginner of user is requested to login information, as shown in Figure 4. Thus, this way is possible for protecting confidential data. As mentioned earlier, this system should be used by a wide range of operator levels. Then the user will be given simple description regarding on introduction and key features; objective and application of X-bar & R charts, X-bar & S charts and Histogram, as well as guidelines for using SMEs-SPC to perform simple analysis. It also does have several intriguing features to provide guidelines or information aided by ‘help’ button as shown in Figure 5. These guidelines make use of few key concepts in statistics, which are important to understand when using the system.

The creation of main list or recorded data set in Figure 6 is possible to view all store information. This part allows user to retrieve previous data, modify, continue add and delete data set parameters including sample size, subgroup size, specification limits, date and others. Moreover, the user is also allowed to quickly adding, deleting and renaming main and part folder used in his or her works.

After performing the main and part folder, add variable interface as shown in Figure 6 enable user to fill up either in wording or numeric text regards to subgroup characteristics and control chart setting. Shown in Figure 7 is an interface data entry according to sub-group size (n). Once (n) is set at three in add variable, empty table with three rows are visible automatically to facilitate user to key in data.

The system can perform a set of data table or quality data processes collected at particular day per month. This interface contains update function to delete or edit data. User can express perform correction of value errors in this
part. Control chart regulation list in Figure 8 aimed to reflect the graph output in relation to specifications. These rules can be adjusted to suite the company requirements. Control charts with subgroup size \( (n) \) in Figure 9 will trigger in red or yellow point if abnormal or out of limits occurs. It should be noted that, there are two options of graph to generate which consists of average and range charts \((X \text{ bar } & \text{ R})\) as well as average and standard deviation charts \((X \text{ bar } & \text{ S})\). Control chart shows the variation of values underlying on y-axis versus X-axis. The labels on X axis are sorted either by date, subgroup size or frequency.

Additionally, user are enabled to report any event if control chart rules are violated, through email as shown in Figure 10. This enhancement allow user to create any comment or feedback action associated with the process. This report can include control chart file image, which could be attached in email. The histogram in Figure 11 reports the frequency of measurable data from the process problem. It also indicates the capability of process, shows whether data is falling inside the bell-shaped curve or within specifications as well as target values achievement.

In the final stage of this system, an overall performance report will be generated and it includes control charts, histogram and capability study as viewed in Figure 12. It can be saved as an electronic file by selecting the destination of file and print for company reference.
In addition, the report of process/production performance is presented in a similar or consistent format, which allows the user to show the progress report to customers periodically. It should be noted that, this interface application is only applicable for SMEs-SPC system, to facilitate user in conducting simple statistical analysis. However, there are several parts of SMEs-SPC which could be developed further in order to meet the needs of new user in SME companies or to expand the user base as well as to make it robust.

5. CONCLUSION

In this paper, the SMEs-SPC system development has shown several factors could influence usability of this system from production level. These graphical presentation or user interfaces shown in figures (above) are simple enough and ease of use for them to conduct simple and quick analysis. Another factor, this system attempt to approach SME companies to manage or organize quality data set as efficient as possible, which based on database admin and graphic interface application. This system is applicable to all types of processes, machines and parameters to store the information and data set and subsequently generate the graph. The internal system has demonstrated a data flow mechanism to separate six types of database from interface. Entirely, user is not required to classify all data or information manually. Therefore, in order to remain competitive in business environment, SMEs must continuously adapt to the rapidly changing business strategy. One way is to improve their business practice through the use of latest technology.

As the conclusion, the researchers believe that the utilization of this system may help organization to train and educate their employees on SPC applications, which could become one of the strategies to improve the quality management tools. Future study will concentrate more on the trial runs at the company A and perhaps, in other SME companies, in order to strengthen the application of SPC system and to verify the effectiveness of SPC computer based system rather than traditional SPC practices.

**ABSTRACT**

Forming processes are manufacturing processes based on deformation of raw material applying pressure in one or several stages until getting the final product. Correct forming of parts is very important as any defective part may result in big economical losses, e.g. the return of a complete set of parts or the loss of some clients. Real time human supervision of such high throughput processes is not possible. These processes need to be supervised and controlled by sensor based systems allowing to achieve zero-default forming processes, while minimizing costs and maximizing the throughput of parts. On the other hand, commonly integrated sensors (force and acoustic) do not allow detecting all types of defaults for this kind of applications (i.e. local burrs due to punch micro cracks). Thus, in the framework of our European Craft Pro2Control project, carried out by leading German, French, Italian and Spanish companies, universities and forming industries, we have considered including an artificial vision (AV) system. An AV system may allow better understanding and/or characterization of force and acoustic measurements, while it can detect defaults that the other sensors may not. While acoustic or force sensors provide real-time information, Vision systems are often too slow for the targeted parts throughputs. Because of that, for the AV part of our control system, a high speed FPGA-based smart camera is proposed. This paper presents the smart camera architecture, as well as the methodology of the image processing algorithms selection and implementation on its internal FPGA (electronic real-time processing device based on reconfigurable logics). The needed image processing algorithms have been analyzed, so that the most time consuming ones (early image processing steps, usually parallelizable) are implemented in the FPGA of the smart camera. Those algorithms are the camera geometric distortions correction, image thresholding and (optional) compression, so that corrected binary images (optionally compressed) are delivered through the internal USB connection to a standard PC, where high level less time consuming algorithms complete the image analysis processes. We also present the architecture of the complete multisensor system. And finally, we present the results obtained for the control of a forming production line in a real industrial environment producing mechanical parts for the automotive industry.

**1. INTRODUCTION**

The manufacturing industry plays a vital economic role all over the world. As an example, manufacturing activity in Europe represents approximately 22% of the EU GNP [1] and manufacturing-related activities account for around 75% of the EU GDP [2]. The current market scenario, with the emergence of new developing countries in Asia, is pushing sheet metal component manufacturers to be more and more competitive concerning their production costs. This is mainly due to the fact that the automotive industry is demanding increasingly complex parts, manufactured with lower formability materials, using simpler production processes at higher rates, with stricter quality requirements. As a result, even small variations in the properties of the raw materials or in the process variables can produce low quality parts.

However, good forming of the parts is a very critical factor, as any defective part may result in big economical losses, e.g. the return of a complete set of parts or the loss of some clients.

2. CONTEXT

Pro2Control is a European Craft project formed by a consortium of leading German, French, Italian and Spanish companies, universities, research institutions and forming industries, with the aim of implementing a zero-defect forming control system, trying to minimize development costs and at the same time maximizing the throughput of parts. In order to build a zero-defect control system, an “intelligent control system” has been developed. This control system is based on Knowledge Based techniques (in this case a rule based Expert System), and gives the operator of the machine feedback and advice about the possible errors/mistakes, and what to do in order to correct/prevent them.

This system is fed by data provided by acoustic-force sensors and by an AV system [3]. On one hand, the acoustic-force sensors are useful to detect defects due to mechanical faults in the press (e.g. tooling breakage, bad evacuated parts or material scraps inside the tooling). On the other hand, AV systems are useful to catch undetected defective parts (e.g. localized burrs or geometrical defects and dimensions outside required tolerances).

The industrial end-user partners have defined which parts to control, as well as the maximum processing speed. The two references presented in Figure 1 correspond to two representative flat parts studied at the present research. Their production throughput is about 60 strokes per minute, and two parts are produced per stroke. One of the aims of the Pro2Control project is also to design a control system able to cope with the high throughputs of future presses (about 1800 parts per minute).

![Figure 1: References studied at the present research](image)

In our proposed AV system, an FPGA-based programmable intelligent camera (Figure 2) with a USB 2.0 connection has been built. The bottleneck algorithms are implemented in this camera, and the on-board processing results sent to the PC. In the rest of the paper, this mixed architecture, as well as the developed algorithms and obtained results are presented.

2.1. OBJECTIVES OF THE AV SYSTEM

The main purpose of the AV system is to evaluate the quality of the produced parts, reject the defective parts and continuously inform the intelligent control system about the quality of the parts. The defects that can be detected by the AV system can be divided into two main groups: those visible from above, e.g. dimensions outside tolerances; and those visible laterally, e.g. non-planar parts, parts with localized burrs and thickness outside tolerance. Therefore, the
AV system involves two iCam cameras that take one picture each (upper and lateral views) of every controlled part [4].

The complete AV system is composed of two “iCam” cameras and a PC. The AV system is mounted on a ramp, where the parts fall after leaving the press. The images are processed and, depending on the quality of the part, a sorting device rejects the low quality parts (Figure 3).

3.- DESIGNING AND VALIDATING THE IMAGE PROCESSING ALGORITHMS IN A PC

Before implementing the image processing algorithms in the “iCam” FPGA, we have designed and validated them on a PC. This way, we can detect the bottleneck algorithms, i.e. the most time consuming ones.

As the AV system has to analyze the geometric dimensions with high accuracy, the first step is the geometric distortions correction. We have extracted the internal camera parameters by observing a chess grid pattern from multiple views, using Zhang's method [5], and OpenCV *ad-hoc* libraries. This process is made off-line, and provides a distortion map. Furthermore, a program has been implemented that allows to extract the external parameters of the camera, using a novel method [6], so that the upper view camera can be positioned parallel to the observed surface, minimizing perspective deformations.

After the geometric distortions have been corrected, the image is thresholded and all contours are detected and filtered depending on their size, in order to detect the part contour without being sensitive to image noise. We calculate the bounding box of the part, and extract the part’s external circular contour points, in order to find the centre of the part. A least squares circle fitting of these contour points is performed in two steps. The first one computes an initial estimation of the centre, and the second step deletes points that do not belong to the fitting circle, allowing to refine its estimation (Figure 4). Finally, the dimensional features to be controlled are extracted using image analysis algorithms and the pixel to mm transforms provided by the calibration step [5,6].

Figure 5 shows the different image processing algorithms implemented. They can be decomposed into 3 steps: 1) part detection, filtering and distortion correction, 2) part centre detection, and 3) dimensions calculation.

The image processing algorithms have been implemented and tested for both selected parts types (see Figure 1) on a PC (Pentium 4 at 3Ghz) using OpenCV libraries (for image processing), and Gtk libraries (for Graphic User Interfaces). The processing time of each algorithm has also been evaluated.

4. VISION SYSTEM: A HARDWARE/SOFTWARE CO-DESIGN ARCHITECTURE APPROACH

FPGAs are programmable electronic targets based on logic elementary blocks. The main features provided by FPGA-based implementation of data, signal or image processing (when possible, opposed to microprocessors or DSPs) are the following [17]:

- Processing times are reduced by a factor 10 with respect to an implementation on DSP, and 100 if compared to an implementation on a microprocessor [7].
- FPGAs allow to fit the hardware implementation architecture and the structure of the implemented algorithm (algorithm architecture adequacy to optimize the implementation).
- Architectures based on FPGAs permit higher capacity of miniaturization.
- FPGAs architectures are re-programmable.
- FPGA-based architectures provide higher confidentiality protection.

Implementing advanced algorithms on FPGAs is not an easy task, compared to the same implementation on regular PCs, as it requires advanced skills in the fields of both image processing and electronics. The language selected to implement the algorithms is VHDL. It is an advanced implementation language intended to describe hardware architectures. The design of a proper implementation needs to make a thorough electronics design and is generally performed under strong development constraints given by the used hardware architecture and its resources (available logical elements and memory) or by the targeted application (processing times required, algorithm complexity, operands precision). To cope with them, solutions like parallel processes implementation, “pipeline” architectures suited to the input data flow, algorithm architecture optimization, implementation of hierarchic sequencing architectures, can be involved.

![Figure 6: “iCam” architecture](image)

While smart cameras based on standard embedded microprocessors (e.g. PowerPC) or DSPs are now available commercially and allow reaching a new range of real time performances [8], finding smart cameras based on FPGAs or IPs in VHDL for advanced image processing is more difficult. Standard in-camera processing functions for commercially available FPGA-based cameras are: sensor configuration (e.g. gain, offset), Region of Interest programming, image subsampling, thresholding or image convolution. Many research teams are facing the problem of implementation of advanced image processing algorithms on FPGA or developing FPGA-based smart cameras [9,10],
defining direct co-design tools for the rapid prototyping and the implementation of distributed real time applications on mono or multicomponent architectures [11,12], or defining direct generic VHDL synthesis tools [13].

Delta Technologies has been facing image processing applications demanding extremely high processing rates (seeds production control of 1000 sunflower seeds per second, image processing on satellites at the acquisition rate of the future hyperspectral satellites, high speed obstacle detection for vehicles using dense stereovision required to run at 100Hz [14,15,16]). To solve these problems, the corresponding image processing algorithms architectures have been adapted for implementation on camera’s FPGA and several smart FPGA-based cameras have been built. Figure 6 presents the current architecture of the “iCam” camera.

We aim at coping with the throughputs of future presses and want to reach a potential throughput of 1800 part per second. From the results presented in Table 1, we can conclude that the bottleneck, corresponds to Step 1 algorithms, i.e. the ones corresponding to the geometric distortion correction and noise filtering. The corresponding algorithms are highly parallelizable and thus should be implemented in the camera’s FPGA. Step 2 algorithms processing times are small and compatible with the targeted processing times. Thus, although they are highly parallelizable, they are run in the PC. Step 3 processing times are also compatible with the throughputs we aim at. The corresponding algorithms' standard architectures are not well suited for FPGA implementation, because of their complex decisional structure, so they are implemented in the PC at this stage of our work.

5.- IMPLEMENTATION OF THE IMAGE PROCESSING ALGORITHMS ON FPGA

The used CMOS sensor provides 10 bits data. We have implemented the following algorithms on the camera’s FPGA:

- **Distortions correction**: when the correction of distortions is activated, we reduce the pixel resolution down to 8 bits due to constraints on the pixels memory buffering involved.

- **Image thresholding**: the output is a binary image (1 bit/pixel). Implementation of this process is straightforward and thus it will not be addressed in this paper.

- **Binary image compression (Optional).**

5.1. - CORRECTION OF THE “ICAM” DISTORTION

On-board the camera, we consider the distortion correction in pixel coordinates, in order to avoid transforming pixels into real world coordinates (i.e. when the image plane of the camera is parallel to the observed surface the pixel/world unit rate is constant) [6].

To correct the distortions, several strategies are possible. A simple one consists in saying that the corrected and distorted image have the same size (NbLin, NbCol) and that the pixels co-ordinates values can only be included in [0, NbLin-1] and [0, NbCol-1]. This may lead to (small) changes of the field of view, but simplifies the algorithms by avoiding to manage image mapping / size change algorithms.

For our pipeline on-board implementation, two approaches where possible (see figure 9):
• Use transform T to compute the corrected pixel position for each incoming pixel of the input distorted raw image. This approach seems the most efficient from a real time point of view, as it would allow to compute the transform as soon as a single input image pixel is available. This approach has two major drawbacks: (1) it implies inverting the classical distortions equations, and (2) it may lead to “holes” in the resulting corrected image (the process does not guarantee that every pixel in the corrected image is computed), or even to distinct pixels of the corrected image to project on the same pixel of the distorted (raw input) image.

• Thus, we decided to use transform T’ instead, in an algorithm where each pixel position in the corrected non distorted image is considered, and we compute the corresponding pixel position in the raw image. From this position in the raw image, we can then compute the grey level of the considered pixel in the corrected image by considering the grey levels in the neighbourhood of its projection in the raw image. We used as typical neighbourhoods elementary cells of $2^N$ pixels, with $N=2, 3$ or $4$.

![Figure 8: Radial distortions correction](image)
![Figure 9: Image transformation](image)

To compute the positions of the corrected non-distorted pixels positions, we encoded the polynomial corrections into distortions correction tables, downloaded via USB to the “iCam” camera. These tables have to be stored in non volatile memory, i.e. Flash memory. But Flash memory has a limited bandwidth (in our case, 10Mbytes/s while the camera sensor frequency is 40MHz) and depending on the required real time performances, it may be necessary to transfer the tables to memory with a better bandwidth (external RAM on-board the camera in our case, with bandwidth around 400 Mbytes/s).

When computing the value of pixels along a given line of the corrected image, we may need pixels of the distorted (original input) image located in the grey areas (Figure 10). In our pipeline computation implementation, we manage a constant input image buffer size; to define this (maximum) size, we need to know what the maximum amplitude (in number of lines) of the distortion is. We also had to discuss which kind of available memory we should use for the real time storage of the pipeline incoming image pixels buffer (Figure 10). Embedded M4K in our FPGA (52 embedded buffers of 512 bytes each) allow parallel access to all memory elements and makes the design simpler (the design is more complex if you use external RAM for example), but their limited number sets an upper limit to the maximum distortion (and thus incoming image pixels buffer) the system can cope with.

![Figure 10: Maximum distortion size defines the size of original image buffer in the pipeline process](image)
5.2. **Image Compression**

This step processes binary images. We have studied several approaches to implement this step on FPGA:

- A first way to implement this compression is to represent the compressed image by chains of numbers of successive pixel of the same level (’0’ or ’1’). We need to be compatible with the maximum case of an image where all pixels have the same level.

- Using a similar approach but compressing the image line by line is more efficient. For each line, we need an additional signal (“end of line”).

We also have to represent the level (’0’ or ’1’) of the successive pixels. We could think of adding a bit to each number encoding the successive pixels having the same level. A more efficient way is to choose a default initial level and to use a bit flag to represent the two possible cases (initial image pixel level is the default level or not).

Those two approaches are not very efficient as they involve the manipulation of large integers (encoded on a large number of bits). Instead, we have decided to manage 8 bits data, and, as we also need to encode at which level (’0’ or ’1’), the successive pixels are, we use one bit (say, the first one) to encode this information. If the number of successive pixels having the same level exceeds $2^7-1=127$, then we will have several successive 8 bits numbers encoding pixels having the same level (’0’ or ’1’), encoded by the first bit.

6.- **Results**

The “iCam” camera has been built and tested in an AV system (see Figure 3). As explained earlier, there are two “iCam” cameras in this prototype. The first one (upper view) measures dimensions A, B, C and D (see Figure 1); the second one (lateral view) measures the localized burrs.

<table>

</tbody>
</table>

Table 2 summarises the results achieved with the upper camera during the testing period in a company. The table specifies, out of 3120 measurements, for each measured part dimension, the lower and upper tolerances, the average value of each dimension, the standard deviation of each dimension and the percentage of “false negatives” and “false positives” achieved for each dimensions. The most important values in the table are the standard deviation (that represents the variability of the measurements) and the “false negatives” and “false positives”. The “false negative” items are the number of times that good quality parts were classified as bad parts, and the “false positive” items are the number of times that bad quality parts were classified as good parts (this never happened because no defective parts were produced during the testing period). The presence of local big burrs, due to punch micro cracks, is also now consistently detected by the lateral view camera.

7.- **Conclusion**

This paper deals with the construction of a global control system for metal forming processes, based on Artificial Intelligence techniques. Two types of sensors are used by the control system: force/acoustic monitoring system and an AV system. Details about the AV system are explained, in particular, its mixed co-design architecture based on two smart FPGA-based cameras and a PC.

An intelligent camera (called “iCam”) has been built, where the bottleneck AV algorithms (e.g. thresholding, camera distortion compensation and optional image compression) are implemented on FPGA. The processing steps embedded on-board the camera are executed in real time, at the maximum pixel acquisition rate (40 MHz). Presently,
the rest of the image processing algorithms are implemented on a PC communicating with the “iCam” through a USB 2.0 link. The image processing algorithms on PC only take an extra time of 5 msec.

Finally, the “iCam” camera is fully customizable via a USB proprietary software, allowing to set image acquisition and processing parameters and to recover images and processing results in the PC.

Implemented algorithms as well as obtained results are presented. Our approach provides a fully mastered development, and guarantees durability and maintainability of the system, as well as it maximizes the throughput, making it possible to cope with the cadences of future presses (around 1800 parts/min).

A Service Target Method for Lead Time Quotation in Assembly Systems

R. Ghasemy Yaghin, S.M.T. Fatemi Ghomi
Department of Industrial Engineering
Amirkabir University of Technology
Tehran, Iran

ABSTRACT

This paper presents a method to assign product due dates for assembly systems with uncertain manufacturing and assembly processing times. The parts arrive to the system as dynamic. The product completion time is the sum of system flow time and arrival time. First, through utilizing the longest path analysis in queueing networks, the distribution function of system flow time is computed by Hartley and Wortham’s method [27] and it is shown that the solutions achieved are significantly much faster than those obtained by Adlakha and Kulkarni’s method. Then the product completion time distribution function is computed by the convolution of system flow time and arrival time. Product due dates are assigned by meeting a service target.

1. INTRODUCTION

Time Based Competition (TBC) has become an important manufacturing strategy in recent years. In an increasingly customer oriented marketplace, low cost and high quality are now considered given and the new competitive dimension is time. Global competition is intensifying the pressure for firms to improve levels of customer service as a source of product differentiation in order to gain a competitive edge [1].

Due to advances in manufacturing systems (e.g. FMS, CAM, CIM, etc.) and introduction of the ideal concepts of inventory control systems (e.g. JIT, ZI, etc.), due-date-based scheduling research has received considerable attention in the last decade and a wealth of literature has been reported in this area. An industrial survey of US companies using FMS indicates that meeting due-dates is the most desirable objective of management [2].

Short and reliable due dates are critical to win customer orders for engineer-to-order and make-to-order companies supplying capital goods [3], [4]. These products are often complex assemblies with many stages of manufacture and assembly.

This paper investigates the problem of assigning product due dates for stochastic assemblies. It defines the due date of an order as the lead time plus its arrival time. In this paper, both of them are assumed stochastic variables. The optimization assigns a product due date to meet a delivery service target. They can be computed quickly and give reliable product due dates.

Due date assignment is often a trade-off between earliness and tardiness costs. For example, a contractual tardiness penalty may be invoked if the product is completed after the due date agreed with the customer; the early completion of activities may result in holding costs. Commonly used cost functions which are minimized in assigning due dates include mean absolute lateness (MAL), mean squared lateness (MSL) and sum of the squares of lateness (SSL) [5], [6]. These cost functions penalize early and late completion symmetrically. Asymmetric earliness and tardiness (AET) may penalize tardiness more than earliness [7]. A small number of researches studied due date management from a profit maximization rather than a cost minimization perspective, considering order acceptance decisions [8]. Another important way of assigning due dates is by specifying the probability of completion before due date; that is the service target ([6], [9], [10], [11].

Some survey papers have been concentrated on specific aspects of due date scheduling problems as, for instance [13], [5]. Some methods use non-stochastic estimates of processing time and neglect assembly operations. In general, the shortcomings of these empirical methods are: (1) they lack efficient methods to calculate the coefficients in their due date expressions; (2) they do not provide information on the distribution of the completion time, which is necessary to analyze risk for a capital project [11].
Analytic methods include queuing networks and linear or non-linear programming. The due date is assigned by minimizing a cost function [13], [9], [14], [6], [7], [2].

Recently, methods and tools based on intelligent system, data mining and information technology have been applied in due date management environment.

The above analytic and new methods were applied to job shops with stochastic processing times. However, these did not include assembly processes. Yano [17] considered stochastic lead-times in a simple two level assembly system, with different processing time distributions including Poisson and Negative binomial. In multi stage assemblies, Song et al. [10] described a recursive method to set stage due dates to meet specified service targets. Song et al. [11] developed an approximate method to assign due dates by minimizing earliness and tardiness costs or to meet a service target. Figure 1 summarizes some of those well-known methods to assign due dates.

Cheng and Gupta [5] and Soroush [2] express that most analytical studies are limited to “small” problems. This paper describes an analytic method to assign product due dates for complex products in the following directions. First, a common assumption found in the majority of the analytical due-date assignment studies is that job processing times are assumed to be deterministic and known before processing begins. However, in many shops, some or all processing times are random variables, manufacturing and assembly processing times are assumed random variables. Second, an implicit hypothesis in the due date based scheduling research is that transit time in buffers is null, i.e., a part which leaves a machine is supposed to be instantaneously available for the next machine (for example [12]) or deterministic (for example [16]), the transport times between the service stations are assumed to be independent random variables. Azaron et al. [19] developed this approach to model assembly systems. Third, in assembly systems completion time is calculated directly and multistage structures are not decomposed into two-stage subsystems. The last issue indicates the solutions achieved by Hartley and Wortham’s method are significantly much faster than those obtained by Adlakha and Kulkarni’s method which also can be useful for real life applications in production scheduling systems.

The remainder of paper is organized as follows. The next section formulates the due date setting problem for multistage assemblies and meeting service target. Section 3 gives a numerical example to demonstrate how the developed method works and efficiency is fully respected for validation studies. Section 4 is computational results. Section 5 is conclusions and recommendations.

![Figure 1: Classification of methods for due date setting](image)

2. PROBLEM FORMULATION

In this section, the completion time distribution function in stochastic assembly systems is computed. Then, by meeting service target, optimal due date is assigned.
Traditionally, material flow analysis in assembly systems has been based on the assumption that the system operates deterministically. In recent years, attention has been directed to a more realistic analysis of assembly systems, explicitly treating the stochastic events that influence operations.

According to procedure, queueing network during a process is transformed to a stochastic one and then lead time distribution function or flow time will be calculated and finally, product due date will be obtained. This algorithm operates sequentially so mean of due date or other moments are calculated. At last through cost minimization of earliness and tardiness and meeting service target the optimal due date will be obtained.

All inter-station buffers are infinite. The time spent in a service station would be equal to the processing time plus waiting in the queue in front of the service station. Therefore, the time spent by a finished product in the system, called manufacturing lead time, would be equal to the length of the longest path of the queueing network whose arc lengths are the transport times between the service stations. The distribution function of the flow time can be approximated by computing the distribution function of longest path in the queueing network.

There are many papers about the longest path analysis in stochastic networks, but not queueing networks. For example, Kulkarni and Adlakha [18] developed an analytical procedure for PERT networks with independent and exponentially distributed activity durations. Fatemi Ghomi and Hashemin [26] generalized the Gaussian quadrature formula to compute longest path function in stochastic networks. Hartley and Wortham [27] developed formulae that may be used to derive the (c.d.f.) "uncrossed" networks. Azaron et al. [19] developed a method for approximating the distribution function of the longest path length in the network of queues by constructing a proper continuous-time markov chain. In this paper, Hartley and Wortham's method was used because of its adaptability with this problem and it is shown that the solutions achieved is much faster than those resulted by Adlakha and Kulkarni's method.

Harrison [20] in a primarily theoretical study, introduced a queueing theoretical model of an assembly operation. Clearly, the arrival process to the manufacturing stations prior to an assembly station is Poisson with the rate of \( \lambda \). Som et al. [22] showed that the input stream the kitting operation is a Markov renewal process. They in a stochastic assembly system have shown that arrival stream of kits (a set of parts which are all needed to perform the assembly) into assembly station, follows Poisson distribution with \( \lambda \) as rate, as long as the parts arrive as a Poisson process of rate \( \lambda \). when unlimited inter-station buffers in size exist, a good estimation of rate \( \lambda \) is gained. In accordance with Song et al. [11], in multistage systems, development of an exact and direct analytic method for allocating delivery due date, because of difficulties in obtaining completion time distribution, is impossible. Therefore the completion time distribution function used in this paper is an approximate one.

### 2.1. NETWORK-BASED DUE DATE SETTING

#### 2.1.1. ASSUMPTIONS

The assembly system is modeled as an open queueing network, where each service station settled in a node of the network represents a manufacturing or assembly operation. One type of product is produced by the system (single product). Processing times of manufacturing and assembly operations are exponentially distributed (including set up times on the service station). Each product consists of a number of different raw parts, which should be processed and assembled to each other. The product order arrives at the source node according to a Poisson process. Then, it is split into some raw materials and each raw part goes to the particular manufacturing station for its first manufacturing operation, instantaneously, according to the same Poisson process with the rate \( \lambda \). If there are parts for being processed, it queues up. After the completion of processing at a manufacturing station, it goes to another manufacturing station to be processed in its routing sequence of manufacturing operations. After completing the manufacturing operations of each part, it is assembled to some other parts in an assembly station. The finished product leaves the system at sink node of the queueing network. Each service station with only one incoming arc represents a manufacturing station. Each service station with more than one incoming arcs represents an assembly station. Having completed one assembly, the server immediately begins another if at least one input item of each part is available. Otherwise, one or more parts have to wait for the last one to arrive (synchronization loss). The reader will recognize that each assembly station is a multi-input generalization of M/M/1 queue. Its salient feature is a very special type of batch servicing, each batch containing exactly one customer of each part. In each service station, there is either one or infinite number of machines with exponentially distributed processing times. Each part has characteristics, which is statistically independent of other parts. The processing time at each service station is independent of preceding processing times. In a non-preemptive setting, once the processing of a job starts, it must be completed without any interruption. Therefore, there are no interruptions due to breakdowns, maintenance, or other such cases.
Customers can be divided into different classes based on the revenues (or margins) they generate, or based on their demand characteristics. In this paper, one kind of customer is studied. Service discipline is FCFS. All inter-station buffers are infinite. The time needed to cross the inter-section buffers may be much greater than the service time and there is no reason to claim that its effect on the system will be negligible. It has been considered deterministic by some papers related to due date (see [16]). The queueing network is in the steady-state. The service rates are the known parameters. The service rate of each service station with one machine is greater than that of product order.

2.1.2. Completion Time Distribution Function

This paper defines the due date of order as the flowtime plus its arrival time; both of them are assumed to be stochastic variables. By applying longest path in queueing networks, the flowtime distribution function is obtained then with convolution, the completion time distribution function is computed.

In network-based due date method, each queueing network is transformed into an equivalent stochastic network with independent and exponentially distributed arc lengths. Then, the distribution function of longest path is computed from the source node to the sink node of this stochastic network by applying the method developed by Hartley and Wortham [27]. The main steps of proposed method are as follows:

Step 1 Compute the density function of the time spent in each service station.

Step 1.1 If there is one machine in the ith service station, then the distribution of waiting time (processing time plus waiting time in queue) in this M/M/1 queueing system is

\[ w_i(t) = (\mu_i - \lambda)e^{-(\mu_i - \lambda)t}, \quad t > 0 \]  

where \( \lambda \) and \( \mu_i \) are the arrival rate and the service rate of this queueing system, respectively. Therefore, the distribution of waiting time in the ith service station would be exponential with parameter \((\mu_i - \lambda)\) [21].

Step 1.2 If there are infinite machines in the ith service station, then the waiting time in this M/M/\( \infty \) queueing system will be exponentially distributed with parameter \( \mu_i \), because there is no queue [21].

Step 2 Transform the queueing network into an equivalent stochastic network by replacing each node that contains a service station with a stochastic arc whose length is equal to the time spent in the particular service station [23].

In this step, it is explained how to replace node \( k \) in the network of queues, which contains a queueing system, with a stochastic arc. Assume that \( b_1, b_2, \ldots, b_n \) are the incoming arcs to this node and \( d_1 \) is the outgoing arc from it. Then, this node is substituted by arc \((k', k'')\), whose length is equal to the system waiting time for the particular queueing system. Furthermore, all arcs \( b_i \) for \( i=1, \ldots, n \) end up with \( k' \) while the arc \( d_1 \) starts from node \( k'' \). Therefore, the network of queues is transformed into a stochastic network. The indicated process is opposite of the absorption an edge \( e \) in a graph \( G \) in graph theory \((G.e)\), see [23] for more details. After transforming all such nodes to the proper stochastic arcs, the queueing network is transformed into an equivalent stochastic network.

Step 3 Transform the original stochastic network, obtained in Step 2, into a new one with exponentially distributed arc lengths.

Step 4 Compute the distribution function of longest path in the new stochastic network obtained in Step 3, following the method of Hartley and Wortham [27].

After computing flowtime function in this way, according to \( d = r + f \) distribution function of product completion time can be achieved by convolution formula [24].

\[ F_D(d) = \int G_R(d-f) dG_F(f) = \int G_R(d-f) dG_F(f) \]

So distribution function of product completion time is as follows:

\[ F_D(d) = \int_0^d G_R(d-f) G_F(f) df \]

where \( D \), \( F \) and \( R \) are delivery due date random variable, flowtime random variable and arrival time random variable, respectively. \( G_F \) and \( G_R \) are cumulative distribution function of flow time and arrival time, respectively.

2.2. Due Date Setting for Assembly Systems: Meeting Service Target

Due date setting is often gained through a trade-off between earliness and tardiness costs. Earliness penalty is holding costs and other costs associated with completing a job before its due date. Tardiness penalty may be invoked if the product is completed after the due date agreed with the customer. This penalty includes loss of goodwill,
expedited shipment, etc. In many situations, a job completion time that deviates further and further from the due date should be assessed a much higher penalty and not just be charged a penalty that is linearly proportional to the deviation. For instance, contracts of aerospace industry may impose tardiness penalties as high as one million dollars per day on subcontractors for aircraft components [25]. The quadratic tardiness penalty is useful in cases where the tardiness cost function is assumed quadratic, although Song et al. considered linear tardiness penalty. For the asymmetric earliness and tardiness (AET), the expected cost is:

$$C(d') = \int_0^\infty e^{-c} (d' - d) F_d'(d) \, dd + \int_0^\infty e^{-c} (d - d') F_d'(d') \, dd$$

(3)

The other important way of assigning due dates is by specifying the probability of completion before due date that is the service target. Due dates are set to match specified service targets. Due date is assigned so that the probability of completing the product before the due date is equal to the service target. A due date \(d\) can be calculated to achieve a specified service target \(p\) as the solution of:

$$F_d(d) = p$$

(4)

For a multi stage assembly system, the distribution is expressed analytically.

In this paper, with quadratic tardiness cost after differentiating and simplifying Eq. 3, the following equation will be gained:

$$F_d(d') = \frac{2e^{-c} \left( \int_d^{\infty} dF_d'(d') \, dd - d' \right)}{c - 2c - d'}$$

(5)

The service targets set to produce plans depends on specific context and assessment of risks. Service targets may be set to meet cost criteria. The above relation indicates that the service target gained from that equation presents a due date plan with the same cost of the procedure explained earlier; minimization of earliness and tardiness costs. If the aim is to minimize the total of earliness and tardiness costs, then Song et al. [11] show that with \(c^+\) and \(c^-\) as the earliness and tardiness penalty costs per unit time, the minimum total cost occurs when the service target \(p = c^-/c^- + c^+\) is used in generating the due date plan. If the cost function is considered to be linear, the minimum total cost occurs when the service target \(p = c^-/c^- + c^+\) is applied which is in full agreement with the work of Song et al. [11].

3. NUMERICAL EXAMPLE

Consider the dynamic assembly system depicted in Figure 2. Service rates and arrival rate are (cost unit is in dollar and time unit is in day):

\(\lambda = 5, \mu_1 = 7, \mu_2 = 6, \mu_3 = 8, \mu_4 = 6, \mu_5 = 9\)

All service stations are \(M/1/M\). The transport times between the service stations settled in nodes 2 and 4, and also between those settled in nodes 3 and 5 are independent exponentially distributed random variables with the parameters \(\lambda(2,4) = 3\) and \(\lambda(3,5) = 1\).

The service station settled in node 5 is assembly station. After assembling, finished product is in hand. The transport times between the other service stations are zero. Now, the queueing network is transformed into the equivalent stochastic network with independent and exponentially distributed arc lengths which is shown in Figure 3.

In this network, the arcs 1, 2, 3, 6 and 7 indicate the waiting times in the \(M/1/M\) queueing systems settled in nodes 1, 2, 3, 4 and 5 of the queueing network with the parameters 2, 1, 3, 1, 4. The arcs 4 and 5 indicate the transport times between the service stations settled in nodes 2 and 4 with parameter 3, and also between the service stations settled in nodes 3 and 5 of the queueing network with parameter 1.

According to the proposed algorithm, the flow time distribution in the multistage assembly is computed as follows:
The arrival time is assumed to be of uniform distribution between zero and 10. The completion time distribution function, according to (6), is then computed as follows:

\[ F_{D}(d) = \int_{0}^{d} G_{F}(d - f) \frac{1}{10} (u(f) - u(f - 10)) df \]

in which \( G_{F}(f) \) is the flow time distribution of the product, \( u(\bullet) \) is the stepwise function and \( F_{D}(d) \) is the completion time distribution function.

\[
F_{D}(d) = \begin{cases} 
\frac{1}{10} \int_{0}^{d} G_{F}(d - f) df, & 0 < d \leq 10 \\
\frac{1}{10} \int_{0}^{10} G_{F}(d - f) df, & d > 10 \\
0, & d \leq 0 
\end{cases}
\]

Now in this instance the completion time distribution function could be obtained in (9). The cumulative graph of completion time is depicted in Figure 4. Table 1 compares the due dates set for different specified probabilities of completion.

\[
F_{D}(d) = \begin{cases} 
0.305 + 0.1d - 0.06e^{-5d} + 0.1823e^{-4d} - 0.525e^{-2d} + 0.633e^{-d} + 0.6e^{-3d} \\
-0.075d^2e^{-4d} - 0.187de^{-4d} + 0.2de^{-2d} - 0.45de^{-2d} + 0.0083e^{-6d} & 0 < d < 10 \\
1 - 0.06e^{-5d} + 0.1823e^{-4d} - 0.525e^{-2d} + 0.633e^{-d} + 0.6e^{-3d} + 0.0667e^{-3d} \\
-0.075d^2e^{-4d} - 0.1875de^{-4d} + 0.2de^{-2d} - 0.45de^{-2d} + 0.0083e^{-6d} - 0.6de^{-3d + 30} & d \geq 10 \\
+0.075d^2e^{-4d + 40} - 1.3125de^{-4d + 40} - 0.2de^{-d + 10} + 0.45de^{-2d + 20} + 0.06e^{-5d + 50} \\
+5.442e^{-4d + 40} - 3.975e^{-2d + 20} + 1.3667e^{-d + 10} + 5.933e^{-3d + 30} - 0.0083e^{-6d + 60} & d \leq 0 
\end{cases}
\]

Figure 5 indicates good agreement between the results of the approximation method of system flow time and simulation results. The differences are of the magnitude of 3.38%.
4. COMPUTATIONAL RESULTS

Hartley and Wortham's algorithm, as mentioned before, calculates the distribution function of longest path through reducing the network by serial and parallel branches and includes rather smooth and clear calculations. However, Kulkarni and Adlakha's algorithm calculates the function through the concept of continuous-time Markov chain and solving differential equation derived from Chapman-Kolmogorov’s equations. In the latter, all the elements in the upper triangle matrix Q should be computed using the logic behind it. This process last several hours for an average scale network. For three test problems each contained three parameter sets, Hartley and Wortham's algorithm is compared with Kulkarni and Adlakha's method. A computer program was written to put the algorithm into action. The program was written in MATLAB 7.1 environment and run on a computer having an AMD Athlon 64 3500+ processor (2.21 GHz) and 1.00 GB of RAM and under windows XP professional. In the worst case (instance 3) it took 104.73 seconds to achieve the solution while under equal situation, Hartley and Wortham’s algorithm took only 1 second (Table 2). This shows the superiority of Hartley and Wortham’s algorithm in both time and quality.

5. CONCLUSIONS AND RECOMMENDATIONS

A product due date assignment procedure has been developed for multistage products with stages of manufacture and assembly. First, by applying the longest path analysis in queueing networks, the manufacturing lead time distribution is computed. Then, the product completion time distribution function is computed. The optimal due date was calculated by meeting service target. Kulkarni and Adlakha’s algorithm has been used in different applications [19]. It was shown that the solutions achieved by Hartley and Wortham is significantly much faster than those obtained by Adlakha and Kulkarni's method, so this method can be used for real life application in production systems.
The method could be further improved to take into consideration bargaining and customer opinions. Another area for the future research is applying the multi objective techniques such as goal programming. This area and several other related areas are being currently studied by the authors.

ABSTRACT

In the literature of multi-objective problem there are different algorithms for solving different optimization problems. This paper presents a min-max multi-objective procedure for a dual-objective, namely makespan, and sum of the earliness and tardiness of jobs in due window problems, simultaneously. In formulation of min-max method when this method is combined with the weighting method, the decision-maker can have the flexibility of mixed use of weights and distance parameter in yielding a set of Pareto-efficient solutions. This research extends the new hybrid metaheuristic (HMH) for solving parallel machines scheduling problems with sequence-dependent setup times which comprises three components: an initial population generation method based on an ant colony optimization (ACO), a Simulated annealing (SA) as an evolutionary algorithm employs certain probability to avoid becoming trapped in a local optimum, and a variable neighborhood search (VNS) which involves three local search procedures to improve the population. In addition, two VNS-based hybrid metaheuristics, which are a combination of two methods, SA/VNS and ACO/VNS, are also proposed for solving the addressed scheduling problems. The non-dominated sets obtained from each of algorithms are compared in terms of various indices, and the computational results show that the proposed algorithm is capable of producing a number of high-quality Pareto optimal scheduling plans. Aside, an extensive computational experience is carried out in order to analyze the different parameters of the algorithm.

1. INTRODUCTION

The problem of scheduling jobs in parallel machines has been extensively investigated during the last decades. Most of the contributions consider a single optimization criterion, although in practice the decision maker (DM) often faces several (usually conflicting) criteria. Therefore, multi-criteria scheduling is considered to be a key research area in order to address the gap between scheduling research and practice [1]. For reflecting real-world situations adequately, this paper formulates multi-objective scheduling problems as two-objective ones which simultaneously minimize the maximum completion time (i.e., makespan), and the minimization of sum of the earliness and tardiness (ET) of jobs in due window problems. No penalty is incurred if a job is completed at any time within its due window.

We consider a bi-objective scheduling of n jobs on an identical parallel machines with sequence-dependent setup times (SDST). Much of the research on operations scheduling problems has ignored setup times but this assumption is commonly observed in various industrial settings including printing, textile, pharmaceutical, chemical and metallurgical industries. Das et al. [2] and Gravel et al. [3] document are examples of sequence-dependent setups in the various industries.

Research in the area of scheduling parallel machines with multiple objectives is limited. Suresh and Chaudhuri [4] proposed a tabu search method to solve a bi-criteria problem involving minimizing maximum completion time and maximum tardiness for unrelated parallel machines. Lin and Liao [5] consider the identical parallel machines problem with makespan minimization subject to minimum total flow time. Angel et al. [6] studied parallel machines scheduling problem with the objectives of minimizing the makespan and total weighted flowtime of jobs. They show that it is possible to construct in polynomial time an approximate Pareto curve whenever the number of machines is a constant. Cochran et al. [7] propose a two-stage multi-population genetic algorithm to solve the parallel machines scheduling problem with two objectives: makespan and total weighted tardiness. They use the genetic algorithm to assign jobs to machines and then sequence them based on the different heuristics proposed in that paper for each objective. Moreover, Yu et al. [8] propose a two stage

¹ Corresponding author: E-mail addresses: fatemi@aut.ac.ir
Lagrangian Relaxation Heuristic method to solve the unrelated parallel machines scheduling with consideration of the three objectives: total completion time, total tardiness, and total number of tardy jobs.

The parallel machines scheduling problem of minimizing total earliness and tardiness with a common weight for earliness and tardiness, respectively, as well as given sequence-dependent setup times for the jobs is treated by Sivrikaya-Serifoglu and Ulusoy [9]. Machines are either identical or uniform. For this problem, two genetic algorithms were given and tested on problems with up to 60 jobs and four machines. Heady and Zhu [10] minimized the total weighted deviation of the completion times from the given due dates, where machines may be unrelated and sequence dependent setup times are given. Lam and Xing [11] gave a short review of new developments of parallel machines scheduling problems associated with setup times of JIT production. Preemption with setup and capacitated machine scheduling. Balakrishnan et al. [12] used a variable neighborhood search formulation that had substantially fewer zero one variables than typical formulations for scheduling problems of this type. Kim et al. [13] attempted to solve the unrelated parallel machines and sequence-dependent setup times with new approach in 2002. In this particular case, the setup times are not machine dependent and each job is composed of \( n \) items. In the line of batch scheduling problems, Kima et al. [14] could be cited, where several search heuristics are presented and tested considering parallel machines. Logendrana et al. [15] deal with the minimization of the makespan, the problem is known to be a NP-hard problem [17].

Thus, the more complex case of bi-objective scheduling problem is also NP-Hard, and consequently, devising a (meta)heuristic to solve this problem is highly desirable. The pur pose of this work is to evaluate the effectiveness of integrating such a specific subset of features into a configurable hybrid metaheuristic (HMH), at least for the class of difficult scheduling problems here considered, consisting of the generalization of the SDST parallel machines scheduling problem. The remainder of this paper is organized as follows. Section 2 is problem description. Section 3 introduces the proposed hybrid algorithm and multi-objective technique that is used in this paper. Section 4 presents the two VNS-based hybrid algorithms used in the experiments. Section 5 presents and compares the hybrid algorithm with version of VNS-based algorithms and VNS algorithm presented recently for SDST parallel machines scheduling. Finally, Section 6 states our conclusions and further researches on this topic.

2. PROBLEM DESCRIPTION

This paper studies the problem of scheduling a set of \( n \) independent jobs on \( m \) identical parallel machines. When a job \( k \) is processed after job \( j \) a setup time \( s_{kj} \) is incurred. All the jobs have a due window \([d_{ij}, d_{ij}]\), where \( d_{ij} \) is the earliest due date and \( d_{ij} \leq d_{ij} \) the latest due date. Furthermore, this paper assumes that the due window is given in advance, i.e., both \( d_{ij} \) and \( d_{ij} \) are prespecified. Each job \( j \in n \) is ready at time \( 0 \) and has a known processing time \( p_j \). If a job \( j \in n \) is completed before \( d_{ij} \), it will incur an earliness penalty and if a job \( j \in n \) is completed after \( d_{ij} \), it will incur tardiness penalty.

3. METHODOLOGIES

3.1. MULTI-OBJECTIVE METHOD: NO PREFERENCE ARTICULATION

Multi-objective optimization problems usually solved by scalarization [18]. Scalarization means converting the problem with multiple objectives into a single objective optimization problem or a family of single objective optimization problems. When a multi-objective optimization problem has been scalarized, methods developed for single objective optimization can be used to solving the problem. The objective function of the single objective problem is called a scalarizing function [19].

The following achievement scalarizing function is minimized subject to the constraint of the problem:

\[
\min \left[ \sum_{i=1}^{n} \left( \frac{f_i(x) - f_i^*}{f_i^*} \right)^p \right]
\]

s.t. \( X \in S \)

\( 1 \leq p \leq \infty \)

The exponent \( p \) gives different ways of calculating the distance. The most frequently used values for \( p \) are 1 for the simplest formulation, 2 for the Euclidean distance, and \( \infty \) for Tchebycheff norm. The difficulty with this approach is finding the value for \( p \) that will maximize the satisfaction of the DM. In this paper, we as sume values for \( p \) are 1, 2, and 100 (as large number instead of \( \infty \)).
In this method the output is just one point on the Pareto front, and the DM has to accept it as the final solution. The optimum, in the min-max sense, gives a solution that treats all the objectives on terms of equal importance, and presents the advantage of being very efficient and easy to implement [20]. Furthermore, when the min-max approach is combined with the weighting method, and by changing the exponent in the distance formulation, the set of Pareto (non-dominating) solutions could be generated for both convex and non-convex problems. This technique was tested with multi-objective engineering design problems found in the literature [21]. For this reason, min-max method with the weighting method was combined to generate various Pareto solutions. Thus, the objective function value is defined by:

$$
\min \left[ w \left( \frac{f_1(x) - f_1^*}{f_1^*} \right) + (1 - w) \left( \frac{f_2(x) - f_2^*}{f_2^*} \right) \right]^{\frac{1}{p}},
$$

where $0 \leq w \leq 1$. $W$ denotes the weight (or relative importance) given to $C_{\max}$ and ET penalties in due window problems. Note that, all instances are solved using 10 different seeds for each algorithm and the minimum solution in all runs is used as $f^*$ for each objective. Then they are replaced in equations (1, 2).

3.2. THE HYBRID METAHEURISTIC APPROACH

The steps of the HMH algorithm are as follows:

Step 1: Generating the initial solution with an ant-sequence: The method starts with generating initial solutions by employing ACO.

Step 2: Intensification phase using VNS. The concept borrowed by the HMH from the VNS is that varying the neighborhood structure during the search process could facilitate the avoidance of traps and enlarge the search scope. In this phase first, the ET value for each neighborhood solution is calculated. VNS works by performing movements that upgrade the solutions. So, the solution that has the minimal ET value is selected as a move. The three neighborhoods employed in our algorithm are defined below:

1. Job swaps on one machine: one machine is chosen and all possible job swaps are considered.
2. Job swaps between two different machines: two machines are chosen and all possible job swaps from different machines are considered.
3. Job transfers from one machine to another: one machine is chosen and all possible job movements from this machine to any other are considered.

Step 3: diversification phase via a SA and VNS. In HMH a SA only is applied to diversification the solution. The asymptotic convergence of SA to a global optimum has been proved, even if such a result has only a theoretical relevance [22]. At iteration, a solution $p_0$ is selected from the neighborhood based on the VNS technique. When each movement is available, unlike VNS techniques, SA executes a second phase where moving from the current solution to a worse solution is allowed with the probability, with the expectation that this movement will eventually guide to a better solution. However, if $p_0$ is not accepted, then neighborhood structure is changed in the same way as in VNS technique (shaking function).

Step 4: Global pheromone update phase and ant generation for next solution by means of ACO. This phase is performed after each ant has completed its schedule. In order to make the search more directed, the global pheromone update with intended to provide a larger amount of pheromone to better schedules.

The basic proposed hybrid algorithm structure is designed as shown in following procedure.

**Hybrid metaheuristic procedure**

1. $R_{\text{time}} \leftarrow$ Set run time()
2. while run time $< R_{\text{time}}$ do
3. $S^* \leftarrow$ Generate initial solution()
4. $l \leftarrow 1$
5. for each ant do
6. $S \leftarrow S^*$;
7. $k \leftarrow 0$
8. $T_i \leftarrow$ Set initial temperature()
9. $T_f \leftarrow$ Set final temperature()
10. while current temperature $> T_f$ do
11. Shake procedure: find a random solution $S' \in N_i (S)$;
12. Perform a local search on $N_i (S')$ to find a solution $S''$;
13. if $f(S') \leq f(S^*)$ then $S^* \leftarrow S''$;
14. $l \leftarrow 1$
15. else
16. $l \leftarrow l + 1$
17. $T_i \leftarrow T_i * \alpha$
18. $T_f \leftarrow T_f / \beta$
19. break
20. $T_i \leftarrow T_i / \gamma$
21. $T_f \leftarrow T_f * \delta$
22. while $T_i > T_f$ do
23. $T_i \leftarrow T_i / \eta$
24. $T_f \leftarrow T_f * \zeta$
25. end while
26. $S \leftarrow S' * (1 - \rho)$
27. $S \leftarrow S' + \sigma$
28. end while
29. $S \leftarrow S^*$
30. end for
31. end while
32. end while
33. end while
34. end for
4. VNS-BASED HYBRID ALGORITHMS

This section illustrates and discusses in detail the proposed two VNS-based algorithms with reference to the following steps that summarize the HMH procedure. In each algorithm the initial solution is generated randomly then combine one the main metaheuristic ACO and SA algorithm with variable neighborhood search. Basically, these hybrids metaheuristic consist of two parts: the construction of a main algorithm and a local search that make with VNS algorithm. Both the phases are repeated in every iteration.

5. EXPERIMENTAL DESIGN

In this section the proposed hybrid algorithms with the VNS algorithm which proposed by Rocha et al. [16] for the SDST parallel machines scheduling with makespan objective are compared. In this work VNS algorithm was adapted to the multi-objective problem. The proposed algorithms and VNS algorithm are coded in C++ and run with an Intel Pentium IV dual core 2.5 GHz PC at 896 MB RAM under a Microsoft Windows XP environment.

5.1. DATA GENERATION AND SETTINGS

The problem data can be characterized by three factors, and each of these factors can have at least two levels. These levels are shown in Table 1.

<table>
<thead>
<tr>
<th>Factor</th>
<th>Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of jobs</td>
<td>6, 30, 100</td>
</tr>
<tr>
<td>Machine distribution</td>
<td>Constant: 1, Variable: Uniform(1, 4), Uniform(1, 10)</td>
</tr>
<tr>
<td>Processing times</td>
<td>Uniform(50, 70), Uniform(20, 100)</td>
</tr>
</tbody>
</table>

The setup times are uniformly distributed from 12 to 24 which are 20% to 40% of their processing time. The setup time matrices are asymmetric and satisfy the triangle inequality. The setup time characteristics follow Rios-Mercado and Bard [23].

5.2. STOPPING RULE

The stopping criterion used when testing all instances with the algorithms is set to a computational time (CPU time) limit fixed to \((m/2) \times (n+1)\) seconds. This stopping criterion not only responsive to number of parallel machines, but also is sensitive toward rise in number of jobs.

5.3. EVALUATION METRIC

After computation of objective value of each algorithm for its instances, the best solution obtained for each instance (which is noted \(Min_{sol}\)) by any of the four algorithms is calculated. Relative percentage deviation (RPD) is obtained by the following formula:

\[
RPD = \frac{Alg_{sol} - Min_{sol}}{Min_{sol}}
\]  

(3)

where \(Alg_{sol}\) is the objective value obtained for a given algorithm and instance.

5.4. EXPERIMENTAL RESULTS

For all problem sizes, instances was tested with \(w \in \{0, 0.2, 0.5, 0.8, \text{ and } 1\}\) in the objective function. Table
2 shows the results of the experiments for two subsets, averaged for each one of the \( n, m \) and \( w \) configurations. The results demonstrate that there is a clear statistically significant difference between performances of the algorithms for \( w \in \{0, 0.2, 0.5, 0.8, \text{and} 1\} \) with \( p=1 \). Figure 1 shows the means plot and LSD intervals (at the 95% confidence level) for four algorithms. Note that, the results of the LSD method helped us identify robust HMH that performed significantly better than others.

![Figure 1: Plots of \( \text{RPD} \) for the type of algorithm factor and \( w \)](image)

5.5. **ANALYSIS OF CONTROLLED FACTORS**

**ANALYSIS OF PROBLEM SIZE FACTOR (NUMBER OF JOBS)** In order to see the effect of number of jobs on two algorithms, a two ways ANOVA is applied. Means plot and LSD intervals (at the 95% confidence level) for the interaction among the factors of type of algorithm, number of jobs, \( w \), and \( p \) are shown in Figure 2. As it could be seen, in the all cases of \( n = 6, n = 30 \) and \( n = 100 \) the HMH works well than all other algorithms.

**ANALYSIS OF M FACTOR (NUMBER OF MACHINES)** Another two ways ANOVA and LSD test are applied to see the effect of magnitude of machines, \( w \) and \( p \) on quality of the algorithms. Figure 3 shows the results. As it could be seen, in the total cases the HMH works better than others.

![Figure 2: Plots of \( \text{RPD} \) for the interaction among the type of algorithm, number of jobs and \( w \)](image)

![Figure 3: Plots of \( \text{RPD} \) for the interaction among the type of algorithm, magnitude of machines and \( w \)](image)

5.6. EVALUATION OF NON-DOMINATED SOLUTION

In this section a quantitative measure is needed for compared sets of Pareto solution. For this reason several approaches in multi-objective literature. This paper proposed four indices as follows:

1. **MID** (mean ideal distance): The closeness between Pareto solution and ideal point (0, 0),
2. **SNS**: The spread of non-dominance solution,
3. **RAS**: The rate of achievement to two objectives simultaneously, and
4. **ALC**: Area under linear regression curve that fits to Pareto solution data with Excel Trendline function ($S_1$ for hybrid algorithm and $S_2$ for VNS algorithm).

The equation of **MID** is defined as follows:

$$MID = \frac{\sum_{i=1}^{n} c_i}{n}$$

where $n$ is the number of non-dominated set and $c_i = \sqrt{f_1^2 + f_2^2}$. The lower value of **MID**, the better of solution quality we have.

**SNS**, as diversity measure, can be expressed by the following equation:

$$SNS = \sqrt{\frac{\sum_{i=1}^{n} \left(MID - c_i\right)^2}{n-1}}$$

The higher value of **SNS**, the better of solution quality we have (more diversity in obtained solution). Another evaluation metric which was proposed in this paper is **RAS**. The equation of **RAS** is represented as equation (6).

$$RAS = \frac{\sum_{i=1}^{n} \left(\frac{f_1}{F_i} - 1\right) + \left(\frac{f_2}{F_i} - 1\right)}{n}$$

where $F_i = \min\{f_{1i}, f_{2i}\}$. The lower value of **RAS**, the better of solution quality we have.

5.7. NON-DOMINATED SOLUTIONS

Figure 4 presents the non-dominated solutions of a single run by multi-objective HMH and multi-objective VNS (for 2 sizes (30×8), and (100×10)). The results show that the proposed algorithm works effectively in both size problems.

6. SUMMARY

In this research to deal with bi-objective optimization the min-max technique is used to solve parallel machine scheduling problems in which they are desired to simultaneously minimize two criteria, maximum completion time and sum of the earliness and tardiness of jobs in due window problems. The core of our method is the novel idea of combining the min-max scalarizing function with the weighting method that he laps to
generate many Pareto and diverse solutions as possible. Several hybrid metaheuristics were proposed for solving addressed problem. The main hybrid metaheuristic that is called HMH has three unique features: It population-based evolutionary searching ability belonging to ACO, it ability to balancing exploration and exploitation belonging to SA, and it local improvement ability belonging to VNS. Experiments with three proposed hybrid metaheuristics and VNS algorithm proposed in a lately published demonstrated that one of them, namely HMM, typically outperforms all others, and it generates the most efficient set of solutions. The future work is to change the objectives that are used in this paper and develop effective hybrid algorithm for other types of scheduling problems.

ABSTRACT

This paper presents an efficient hybrid metaheuristics for scheduling jobs in a hybrid flowshop with sequence-dependent setup times. The problem is to determine a schedule that minimizes sum of the earliness and tardiness of jobs. Since this problem class is NP-hard in the strong sense, there seems to be no escape from appealing to metaheuristic procedures to achieve near-optimal solutions for real life problems. This paper proposes the hybrid metaheuristic algorithm which comprises three components: an initial population generation method based on an ant colony optimization, a simulated annealing as an evolutionary algorithm employs certain probability to avoid becoming trapped in a local optimum, and a variable neighborhood search which involves three local search procedures to improve the population. A design of experiments approach is employed to calibrate the parameters of the algorithm. Results of computational tests in solving on 252 problems up to 100 jobs have shown that the proposed algorithm is computationally more effective in yielding solutions of better quality than the adapted random key genetic algorithm and immune algorithm presented previously.

1. INTRODUCTION

In a just-in-time environment, each job should be completed as close as possible to its due date. Traditionally, tardiness penalties due to delivery after a contractually arranged due date are considered. Missing a job’s due date may result in the loss of the customer or the need to compensate for the delay by a long time production or assemby line. On the other hand, producing a job much earlier than its due date may cause unwanted inventory and/or deterioration of the product. In such an environment, the length a job is tardy or early is important [1]. Therefore, tardiness together with earliness penalties are considered to meet the requests of practice and any schedule of a set of jobs should strive to minimize the total earliness and tardiness where tardiness reflects customer satisfaction and earliness measures inventory performance [2].

A hybrid flowshop model, commonly known as flexible flow line, allows us to represent most of the production systems. The process industries such as chemical, pharmaceutical, oil, food, tobacco, textile, paper, and metallurgical industries can be modeled as hybrid flowshops. A hybrid flowshop consists of a series of production stages, each of which has several facilities in parallel [3]. The flow of products in the plant is unidirectional. Hybrid flowshop models differ in the type and number of machines at the stages.

Scheduling problems with sequence-dependent setup times (SDST) are among the most difficult classes of scheduling problems. Sequence-dependent setup times of a hybrid flowshop system is even more challenging. Although there has been some reported progress, the understanding of sequence-dependent setups, however, is still believed to be far from being complete [4]. Therefore in this paper, sequence-dependent setup time restrictions are taken into account as well.

This paper proposes a hybrid algorithm to SDST hybrid flowshop problems. The paper has the following structure. Section 2 gives the brief literature review. Section 3 is the problem description. Section 4 introduces the proposed hybrid algorithm. Section 5 presents the experimental design which compares the results achieved by proposed hybrid algorithm with those achieved by past genetic algorithm and immune algorithm. Finally, section 6 is devoted to conclusions and future works.

2. LITERATURE REVIEW

Most of the studies deal with problems with throughput related measures, such as minimizing makespan or mean flow time, but there are not many studies on problems with performance measures related to due dates.

1 Corresponding author: E-mail addresses: fatemi@aut.ac.ir
Adenso-Diaz [5] proposed a hybrid algorithm based on Simulated Annealing (SA) and tabu search (TS) in which the solution of SA was used as initial one by TS method where the size of the neighborhood was limited, and they compared the solution obtained against a tabu search starting from the same initial solution without any restriction in the size of neighborhood. Brah [6] investigates performance of ten priority rules in terms of mean and maximum tardiness, and Lee et al. [7] suggest heuristic algorithms for hybrid flowshops with the objective of minimizing total tardiness. Allouati and Artiba [8] addressed the FFm/STsi problem with respect to the criteria of Cmax, Tmax, Tj, and Cj with machine unavailability intervals (due to breakdowns or eventive maintenance), where the transportation times between the stages are explicitly considered. Jungwattanakit et al. [9] considered the FFm/STsi/STsd problem for the case of unrelated parallel machines, where \( \theta \leq 1 \). They adapted the well known constructive heuristics and iterative heuristics (genetic algorithm and simulated annealing) for the pure flowshop problems.

While many solution procedures have been developed over many years to solve the scheduling problems, only some attempts have been made to develop procedures for the hybrid flowshop problem with sequence dependent setup times of jobs (see for instance the recent review on scheduling with setup times by Allahverdi et al. [10]). However, in most real world cases, the length of the setup depends on the job sequences, which is separable from processing. There seems to be published only three works addressing heuristics for flexible flowlines with sequence dependent setup times. Pugazhendhi et al. [11] addressed the FFm/STsi/\( \sum w_j f_j \) problem, where some jobs may have missing operations on some machines. They proposed a heuristic procedure to derive a non-permutation schedule from a given permutation sequence. Kurz and Askin [12] examined scheduling rules for SDST flexible flowlines. They explored three classes of heuristics.

Moreover, Kurz and Askin [13] formulated the SDST flexible flowlines as an integer programming model. Due to the difficulty of solving the IP model directly, they developed a random keys genetic algorithm. They created a lower bound to evaluate the heuristics. Zandieh et al. [14] proposed an immune algorithm, and showed that their algorithm outperforms the random keys genetic algorithm of Kurz and Askin [13].

3. DESCRIPTION OF PROBLEM AND NOTATION

Let \( g \) be the number of stages and \( m' \) be the number of machines in parallel at each stage \( t \). These machines are identical. There are \( n \) independent jobs that are available at time 0, to be scheduled without preemption. A machine can process at most one job at a time and a job can be processed by at most one machine at a time. Each product is processed at only one facility in each stage and at one or more stages before it exits the plant. The problem consists of assigning jobs to machines at each stage and sequencing the jobs assigned to the same machine so that some optimality criteria are minimized. The jobs can wait in between stages and the intermediate storage is unlimited. The setups are assumed to be sequence-dependent. This paper supposes that machines are initially setup for a nominal job 0 at every stage. Job \( n+1 \) exists at every stage only to indicate the end of the process, if needed. Let \( d_j \) be the due date for the job \( j \), the earliness and tardiness of job \( j \) are defined as \( E_j = \max(0, \text{Cj} - \text{dj}) \) and \( T_j = \max(0, \text{dj} - \text{Cj}) \), respectively, where \( \text{Cj} \) is the completion time of job \( j \). In particular, the objective function can be written as

\[
\text{Min} \quad Z = \sum_{j=1}^{n} (E_j + T_j) = \sum_{j=1}^{n} |d_j - \text{Cj}|. 
\]

When the objective function is written in this form, it is clear that earliness and tardiness are penalized at the same rate for all jobs.

4. THE HYBRID METAHEURISTIC APPROACH

The construction of hybrid metaheuristics is motivated by the need to achieve a good tradeoff between the capabilities of a heuristic to explore the search space and the possibility to exploit the experience accumulated during the search. When the HMH algorithm is proposed for hybrid flowshop problems, the first important step is the representation of a solution. Bean [15] introduced a random key approach for real-coded GA for solving sequencing problem. Subsequently, numerous researchers show that this concept is robust and can be applied for the solution of different kinds of scheduling problems. In this paper, the random key approach is used to represent a schedule incorporated with the hybrid methodology is applied to address problem. Let us no w dis scuss w hich a ccepts h ave been borrowed from Ant Colony Optimization (ACO), Variable neighborhood search (VNS) and SA.

4.1. ANT COLONY OPTIMIZATION

The ACO algorithm is implemented in this paper is basically the Ant Colony System (ACS), but it is pheromone values are limited to a bounded value. Explicit limits on the pheromone values prevent the probability for constructing a solution falls below a certain value greater than 0. This algorithm is called Max–Min Ant System (MMAS). The basic steps of the MMAS are presented below:
Step 1: Initialize the pheromone trails and parameters:
Step 2: While termination condition is not met do the following:
  • Construct a solution.
  • Improve the solution by local search.
  • Update the pheromone trail or trail intensity, denoted by $\tau_{ip}$, where $\tau_{min} \leq \tau_{ip} \leq \tau_{max}$.
Step 3: Return the best solution found.

In the context of application of the ACO algorithm to scheduling problems, $\tau_{ip}$ denotes the trail intensity (or desire) of setting job $i$ in position $p$ of a sequence. These trails form a kind of adaptive memory of previously found solutions, and are modified at the end of every iteration. It is to be noted that, for every job $i$, for any possible position $p$, a pheromone value is stored and updated in each iteration of the ACO algorithm. Hence, there are $n$ such values of $\tau_{ip}$.

4.1.1. Generating the Initial Solution with an Ant-Sequence

Initially, all $\tau_{ip}$’s are set equal to $\tau_{max}$, where $\tau_{max}$ is set equal to $1/((1 - \rho) \times Z_{best})$ and $\rho$ denotes the persistence of the trail. The term ‘$Z_{best}$’ refers to the best value of objective function that has been obtained so far. At first, $Z_{best}$ equals the objective-function value yielded by the seed sequence. Starting from a null sequence, ant colony algorithm makes use of trail intensities in order to determine the job to be appended in position $p$, where $1 \leq p \leq n$ and $n$ refers to the number of jobs to be scheduled. Although the trail intensity $\tau_{ip}$ changes with respect to every iteration in the ant colony algorithm, the iteration counter is omitted for the sake of simplicity of presentation. An ant starts constructing a sequence by choosing a job for the first position, followed by the choice of an unscheduled job for the second position, and so on. A dummy job ‘0’ is introduced on which an ant is set initially, and the construction of partial sequences begins, thereby leading to the build-up of a complete sequence by the ant, called an ant sequence. In the case of MMAS, the following procedure is used to choose an unscheduled job, say job $i$, probabilistically for position $p$.

Sample a uniform random number $u$ in the range (0,1).
If $u \leq (n-4)/n$ then
among the jobs that are not yet scheduled, choose the job with the maximum value of $\tau_{ip}$;
else
job $i$ is selected, from the set of first five unscheduled jobs as present in the best sequence obtained so far, for position $p$ by sampling from the following probability distribution:
$$E_{ip} = \frac{\tau_{ip}}{\sum_p \tau_{ip}}.$$  \hspace{1cm} (2)

where job $i'$ belongs to the set of first five unscheduled jobs, as present in the best sequence obtained so far. Note that when there are less than five jobs unscheduled, then all such unscheduled jobs are considered.

4.1.2. Updating the Trail Intensities

An ant-sequence is subjected to the position-based local search procedure to enhance the quality of solution. Let the objective-function value of this improved sequence be denoted by $Z_{current}$. Subsequently, trail intensities are updated as follows:
$$\tau_{new} = \begin{cases} \rho \times \tau_{old} + (1/ Z_{current}) & \text{if job } i \text{ is placed in position } p \text{ in the generated sequence;} \\ \rho \times \tau_{old} & \text{otherwise,} \end{cases} \hspace{1cm} (3)$$

Update the best sequence and $Z_{best}$, if the generated sequence is superior to the best sequence that has been obtained so far.

4.2. Variable Neighborhood Search

This method is different from the most local search heuristics in that it uses two or more neighborhoods, instead of one, in its structure. In addition, to avoid costing too much computational time, the best number of neighborhoods is often three [16], which is followed by our algorithm, so index $l$ is defined to show local search type. The three neighborhoods employed in our algorithm are defined below:

1. Job swaps on one machine: one machine is chosen and all possible job swaps are considered.
2. Job swaps between two different machines: two machines are chosen in one stage and all possible job swaps from different machines are considered.
3. Job transfers from one machine to another: one machine is chosen and all possible job movements from this machine to any other are considered.
Note that the neighborhoods themselves \((N_i(S), N_2(S)\text{ and } N_3(S), \text{ respectively})\) are determined both by its respective structure and by the solution it is being applied to. The size of neighborhood \(N_i(S)\) is \(O(mn^2)\), neighborhood \(N_2(S)\) is \(O(m^2n^2)\) and neighborhood \(N_3(S)\) is \(O(n^2)\).

VNS always tries to use the fastest local search available first. If after an iteration no improvement is made, then another neighborhood is used \((l\text{ is incremented})\), and every time a new solution is found, the first and the fastest local search is used \((l = 1)\).

### 4.3. Simulated Annealing

SA is inspired by the physical process of heating a substance and then cooling it slowly, until a strong crystalline structure is obtained. This process is simulated by lowering an initial temperature by slow stages until the system reaches to an equilibrium point, and no more changes occur. The main idea of this technique is to start from some initial solution, \(\pi', \text{ and successively move a among neighboring solutions until the stopping condition is satisfied. At each iteration, } \pi' \text{ is selected from the neighborhood of actual solution } (\pi_{iter}) \text{ and it replaces with a probability}

\[
P(t_{iter}, \pi_{iter}, \pi') = \min \left\{ 1, \exp\left(\frac{-f(\pi') - f(\pi_{iter})}{t_{iter}}\right) \right\}
\]

where \(t_{iter}\) is a parameter called the temperature at iteration \(iter\). The temperature decreases during the search process according to the cooling scheme. The performance of SA depends on the following parameters, which have to be precisely selected:

#### 4.3.1. Initial Temperature

The initial temperature is selected on the basis of \(K = nm + 1\) solutions \(\pi_0; \pi_1; \ldots; \pi_K\), where \(\pi_j\) is randomly selected from the neighborhood of \(\pi_{j-1}\) and \(\pi_0\) is an initial solution. The initial temperature is defined as

\[
t_0 = \frac{\delta}{mn},
\]

where \(\delta = \max_{j=1,\ldots,k} \{f(\pi_j) - f(\pi_{j-1})\}\).

#### 4.3.2. Cooling Scheme

The temperature changes in every iteration according to the logarithmic cooling scheme:

\[
t_{j+1} = \frac{t_j}{1 + \lambda t_j},
\]

where parameter \(\lambda\) is defined as

\[
\lambda = \frac{\ln(t_f) - \ln(t_j)}{f/2}.
\]

and \(f\) is the total number of iterations. The final temperature \(t_f\) is determined from the following expression:

\[
t_f = \frac{\phi}{nm}.
\]

### 4.4. A Hybrid Method

The basic proposed hybrid algorithm structure is designed as below.

**Hybrid metaheuristic pseudocode**

1: \(R_{time} \leftarrow \text{Set run time}()\)
2: while run time < \(R_{time}\) do
3: \(S^* \leftarrow \text{Generate initial solution}()\)
4: \(l \leftarrow 1;\)
5: for each ant do
6: \(S \leftarrow S^*;\)
7: \(k \leftarrow 0;\)
8: \(T_k \leftarrow \text{Set initial temperature}()\)
9: \(T_f \leftarrow \text{Set final temperature}()\)
10: while current temperature > \(T_f\) do
11: \(\text{Shake procedure: find a random solution } S' \in N_i(S);\)
12: \(\text{Perform a local search on } N_i(S')\text{ to find a solution } S'\);\)
13: if \(f(S') \leq f(S^*)\) then
14: \(S^* \leftarrow S'\);
15: \(l \leftarrow 1;\)
16: else
17: accept $S'$ as new solution with probability $p(T_k, S', S^*)$
18: end if
19: Adapt temperature($T_i$)
20: $l \leftarrow l + 1$
21: end while
22: generate schedule
23: evaluate schedule
24: end for
25: verify for global or local best
26: evaporate pheromone in all trials
27: deposit pheromone on best global schedule
28: end while

4.5. STOPPING RULE

The stopping criterion used when testing all instances with the algorithms is set to a computational time (CPU time) limit fixed to $(n^2 \times \sum_{t=1}^{g} m' / g) \times 3$ milliseconds. This stopping criterion is not only responsive to the number of stages, but also is sensitive towards the rise in number of jobs and number of machines at each stage.

5. EXPERIMENTAL DESIGN

In this section the proposed hybrid algorithm with the RKGA proposed by Kurz and Askin [13] and immune algorithm (IA) which proposed by Zandieh et al. [14] for the SDST hybrid flowshop scheduling are compared. These algorithms originally were proposed for makespan objective, so, these algorithms for ET objective problems are adapted. All algorithms are coded in C++ and run with an Intel Pentium IV dual core 2.5 GHz PC at 896 MB RAM under a Microsoft Windows XP environment.

5.1. DATA GENERATION AND SETTINGS

An experiment was conducted to test the performance of the hybrid algorithm. Following Kurz and Askin [12], data required for a problem consists of the number of jobs, number of stages, number of machines in each stage, range of processing times, and the range of sequence dependent setup times. The problem data can be characterized by five factors, and each of these factors can have at least two levels. These levels are listed in Table 1.

<table>
<thead>
<tr>
<th>Factor</th>
<th>Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of jobs</td>
<td>6, 30, 100</td>
</tr>
<tr>
<td>Machine distribution</td>
<td>Constant: 1, Variable: Uniform(1, 4), Uniform(1, 10)</td>
</tr>
<tr>
<td>Number of stages</td>
<td>2, 4, 8</td>
</tr>
<tr>
<td>Processing times</td>
<td>Uniform(50, 70), Uniform(20, 100)</td>
</tr>
<tr>
<td>Skipping probability</td>
<td>0.00, 0.05, 0.40</td>
</tr>
</tbody>
</table>

In general, all combinations of these levels are tested. However, some further restrictions are introduced. The variable machine distribution factor requires that at least one stage has a different number of machines than the others. Also, the largest number of machines in a stage must be less than the number of jobs. Thus, the combination with 10 machines at each stage and 6 jobs will be skipped and the combination of 1–10 machines per stage with 6 jobs will be changed to 1–6 machines per stage with 6 jobs. There are 252 test scenarios and ten data sets are generated for each one.

Another important issue is the due dates of the jobs. To generate due dates of all $n$ jobs the following steps is proposed:

1. Compute total processing time of each job on all $g$ stages.

   \[ p_i = \sum_{j=1}^{g} p_{ij}, \forall i \in N \]  

   \[ (9) \]

2. Compute average setup time for all possible subsequent jobs and sum it for all $g$ stages.

   \[ s_i = \sum_{j=1}^{n} \sum_{k=1}^{n-j} \frac{S_{jk}'}{n-1}, \forall i \in N \]  

   \[ (10) \]

Determine a due date for each job.
\[ d_i = (1 + \text{random} \times 3) \times \left( \frac{g}{\min_{m' \in M} (m')} \right) \times (s_i + p_i), \; \forall i \in N \]  

where \text{random} is a random number from a uniform distribution over range \((0, 1)\). This method of generating due dates results in very tight to relatively tight due dates.

### 5.2. Hybrid Algorithm Parameters Tuning

The efficiency of a hybrid algorithm depends on the choice of the best parameters in order to prevent premature convergence, to ensure diversity in the search space, to intensify the search around interesting regions, etc. This section describes an empirical testing approach for finding the best tuning parameters of our hybrid algorithm. In order to reduce the number of combinations, some parameters of the HM are fixed a priori based on the claims suggested in the literature. Parameters tuning is applied only for the minimum values for trail intensity \(\tau_{\min}\) with two levels \(1/5 \tau_{\max}\) and \(1/10 \tau_{\max}\), persisting the trail intensities \(\rho\) with three levels \((0.8, 0.9\) and \(0.95)\) in ACO, initial temperature parameter \(\varphi_1\) with \(0.7, 0.9\) and \(\text{Uniform} (0.5, 1)\) and final temperature parameter \(\varphi_2\) with three levels \((0.01, 0.1\) and \(\text{Uniform} (0, 0.1)\)) in SA algorithm.

54 different hybrids are obtained by these levels. Six instances are generated randomly, 2 small, 2 medium and 2 large, for each combination of \(n, m, SDST\) resulting a total of 252 instances. All these instances are solved by 54 different hybrid algorithms. The results are analyzed by the means of multi-factor Analysis of Variance (ANOVA) technique. The three main hypotheses for the validity of ANOVA, i.e.: randomness and independence, normality, and homogeneity of variance have been tested. That was done and founded no bias for questioning the validity of the experiment (see Montgomery [17]). Table 2 shows the results for different sizes of problems; small, medium and large.

<table>
<thead>
<tr>
<th>Parameters</th>
<th>Small</th>
<th>Medium</th>
<th>Large</th>
</tr>
</thead>
<tbody>
<tr>
<td>(\tau_{\min})</td>
<td>(1/5 \tau_{\max})</td>
<td>(1/5 \tau_{\max})</td>
<td>(1/10 \tau_{\max})</td>
</tr>
<tr>
<td>(\rho)</td>
<td>0.9</td>
<td>0.95</td>
<td>0.9</td>
</tr>
<tr>
<td>(\varphi_1)</td>
<td>Uniform ((0.5, 1))</td>
<td>Uniform ((0.5, 1))</td>
<td>Uniform ((0.5, 1))</td>
</tr>
<tr>
<td>(\varphi_2)</td>
<td>Uniform ((0.01, 1))</td>
<td>0.01</td>
<td>0.01</td>
</tr>
</tbody>
</table>

### 5.3. Evaluation Metrics

After computation of \(\sum (E + T)\) of each algorithm for its instances, the best solution obtained for each instance (which is named \(\text{Min}_{\text{sol}}\)) by any of the three algorithms is calculated. Relative Percentage Deviation (RPD) is obtained by the following formula:

\[
\text{RPD} = \frac{\text{Alg}_{\text{sol}} - \text{Min}_{\text{sol}}}{\text{Min}_{\text{sol}}} 
\]  

where \(\text{Alg}_{\text{sol}}\) is the \(\sum (E + T)\) obtained for a given algorithm and instance.

### 5.4. Numerical Result

The results of the experiments for three subsets, averaged for each one of the \(n\) and \(g\) configurations are shown in Table 3. Each instance is solved using 6 different seeds and the average solution is considered.

As it can be seen, the hybrid algorithm provides better results than RKGA and IA. In order to verify the statistical validity of the results shown in Table 3 a design to confirm which the best algorithm is, a design of experiments and an analysis of variance (ANOVA) is performed where the different algorithms are considered as a factor and the response variable RPD.

5.5. **ANALYSIS OF CONTROLLED FACTORS**

**ANALYSIS OF PROBLEM SIZE FACTOR (NUMBER OF JOBS)** In order to see the effect of number of jobs on three algorithms, a two ways ANOVA is applied. Means plot and least significant difference (LSD) intervals (at the 95% confidence level) for the interaction between the factors of type of algorithm and number of jobs are shown in Figure 1.

![Figure 1: Plot of RPD for the interaction between the type of algorithm and number of jobs](image)

As it could be seen, in the all cases of \( n = 6, n = 30 \) and \( n = 100 \) the HMH works better than RKGA and IA.

**ANALYSIS OF G FACTOR (NUMBER OF STAGES)** Another two ways ANOVA and LSD test are applied to see the effect of magnitude of stages on quality of the algorithms. The results are shown in Figure 2. As it could be seen, in all cases the hybrid algorithm works better than RKGA and IA.

**ANALYSIS OF M FACTOR (NUMBER OF MACHINES)** Another two ways ANOVA and LSD test are applied to see the effect of magnitude of machines on quality of the algorithms. The results are illustrated in Figure 3. As it could be seen, in all cases the hybrid algorithm works better than RKGA and IA.

6. **SUMMERY**

This study has addressed the problem of scheduling in the hybrid flowshop with sequence-dependent setup time. For the objective of sum of the earliness and tardiness about a due date of jobs, the hybrid metaheuristic algorithm which combines ACO, SA and VNS in a population-based context is suggested. For each new generation of schedules, the key is to use hybridizing the population-based evolutionary searching ability of ACO with the local improvement ability of some VNS and SA to balance exploration and exploitation. In the proposed HMH, the balance between the global exploration and the local exploitation was stressed. This approach generated new individuals that can effectively guide and speed up the search.

When tested on many problem instances, this model proved to be efficient and robust. The computational results for test problems with different structures indicate that the HMH provides good average results for many test problems compared to the genetic algorithm and immune algorithm proposed in a lately published.

We believe that the contribution of this method is not only the development of a framework by which due-date-related problems can be solved, but also the generality of the framework, as it can solve different categories of scheduling problems readily and with very good performance. For future work, this research can be extended in several directions. For example, this study can be extended to consider other versions of the problems; e.g., single machine or job shop scheduling problems, since general ideas of the algorithm can be easily
implemented in various scheduling problems.

Setting warm-up period in simulation analysis with autocorrelated data

S.M.T.Fatemi Ghomi * and S.Shokuhyar

Department of Industrial and Engineering, Amirkabir University of Technology, 424 Hafez Avenue, Tehran, Iran

ABSTRACT

One means for dealing with initialization bias in simulation experiments is to implement a warm-up period. This requires the correct estimation of the initial transient. In literature many methods has been used to determine the warm-up period for non autocorrelated data. But simulation output data are typically auto correlated. So in this paper auto correlated time series model is applied to select appropriate time series. For doing this, one software is develop to generate partial autocorrelation function and sample autocorrelation function in simulation software to set appropriate parameter for time series. After selecting appropriate time series, control limit for system is set. Then with running simulation model, warm up period will be defined. To apply this method, at least one example is presented.

1. INTRODUCTION

Most simulation runs are started with empty systems. For example, a production line is usually started with no parts in any of the buffers or machines. Since there is no congestion at this time, parts entering such an empty system tend to flow through the system at a faster rate than parts produced during more representative hours. Including information about these early parts will cause to under-estimate the value of most of steady state performance measures such as the average production rate or the mean time spent by parts in the system. This is illustrated in the following Figure1 of the fraction of parts spending more than 60 minutes in a three station flow line for five different simulation runs. Each point represents the average value computed for all parts having left the system at the indicated time. The plot includes all averages for the first 1,000 customers.

Figure 1: Plot of the first 1000 values of the fraction of parts spending more than 60 minutes in a three station flow line for five different simulation runs

It is seen that the observed average fraction always starts out at zero, then increases and eventually converges to

*Corresponding Author :Tel.: (+9821)66413034; Fax: (+9821)66413025; Email address: Fatemi@aut.ac.ir
about 60% - 80%. However, the effect of this initial bias will never be completely eliminated. Also it is seen that each run appears to be quite noisy, but that the average value for each observation appears to be better behaved.

The effect of the initial bias can be eliminated if data collection is not started until the simulation has reached a more representative "steady state". For example, it appears that the bias would be eliminated in the above if the first 300 observations were eliminated [1].

The goal of steady state simulation studies is to estimate the long run characteristics of the system. In order to estimate the long run performance measures, the simulation model is run for a certain period of time. Most of the simulation models are started empty and idle. Almost every time, these conditions differ from the steady state condition. Due to this, the simulation model takes some time to reach steady state. During this time period the model is said to be in transient state. The observations collected during this time period may affect the accuracy of the estimates of the performance measure, if the transient state lasts for a relatively long time. This problem is called as the initialization bias or the startup problem in simulation literature. One of the ways to overcome this problem is to run the simulation model for a time period L called as the warm-up length. Reset all statistics after time L and start recording observations for a period of m - L, where m is the run length. Another difficulty here is in predicting the warm-up length [2].

So the practical question is "How long should the warm-up period be?"

Regarding the above discussion in estimating the steady-state parameters of a simulation model, the correct removal of any initialization bias is of vital importance. There are two methods open to the simulation modeler.

1) - the starting condition of the model can be set such that no bias exists in the output data. This requires the correct setting of the starting condition.
2) - the model can be run for a warm-up period and the data are then deleted from that period (the initial transient). This, of course, requires the correct estimation of the warm-up period. This paper focuses on this latter approach.

The purpose of this paper is to describe a new method to estimate the warm-up period of a steady-state simulation. Before describing this method there is a brief review of the literature on estimating the warm-up period. Then the new method is described. To apply this method, at least one example is presented.

2.Methods to estimate the warm-up period

Various methods have been purposed to identify the initial transient in simulation models. The devised warm-up methods can be categorized under five headings [3]:

- **Graphical methods:**
  These involve the visual inspection of time-series of the output data; such as Welch’s Method [4]. This is the simplest and most general technique used to determine the warm-up length. It is a graphical technique that requires multiple replications.

- **Heuristics approaches:**
  These apply simple rules, with few underlying assumptions.

- **Statistical methods:**
  These rely upon the principles of statistics for determining the warm-up period; such the method used by Yücesan [5]. He presented a method to detect the initialization bias. The method is based on randomization tests. Yücesan formulated the problem of initialization bias in a hypothesis testing framework concerning the mean of the process. Randomization tests are applied to test the null hypothesis that mean of the process is unchanged throughout the run. The advantage of using this method is that, no assumptions, like that of normality are required. The null hypothesis for this method is that there is no initialization bias.

- **Initialization bias tests:**
  These identify whether there is any initialization bias in the data and, therefore, they are not strictly methods for identifying the warm-up period, but they can be used in combination with warm-up methods to determine whether they are working effectively.

- **Hybrid methods:**
  These involve a combination of graphical or heuristic methods with an initialization bias test.

One of the most useful methods to determine the warm-up period is Statistical Process Control (SPC) method to detect when a model is in steady-state [3].

There is a close relationship between the concepts of SPC and those of transient and steady-state in simulation
output analysis. A model that is in steady-state varies about a constant mean according to some fixed distribution, while in transient it does not. As such, a simulation that is in steady-state could be considered to be “in-control”, while during a transient phase it could be considered to be “out of control”. It seems possible; therefore, that the methods employed in SPC could be used to detect when a model is in steady-state, and when it is not [3].

But the main weakness of this method, is that the process requires to be non autocorrelated. Simulation output data are typically autocorrelated and so SPC methods need some assumptions for applying to determine the warm-up period. So in the next section autocorrelated time series model is applied to determine the warm-up period.

3. The proposed model

Conventional control charts are based on the assumption that the observations are independently and identically distributed (i.i.d.) over time.

Numerous control chart modifications have been proposed for monitoring auto correlated processes. But three views can be considered for applying auto correlation in time series data [6]:

1. At one extreme, Wheeler [7] argues that the usual control limits are contaminated “only when the autocorrelation becomes excessive (say 0.80 or larger).” He concludes that “one need not be overly concerned about the effects of autocorrelation upon the control chart.”

2. At the opposite extreme, automatic process control (APC), also referred to as engineering process control, views autocorrelation as a phenomenon to be exploited. In contrast to SPC, which assumes that the process remains on target unless an unexpected but removable cause occurs, APC assumes that the process is changing dynamically due to known causes that cannot be eliminated. Instead of avoiding “over control” and “tampering,” which have a negative connotation in the SPC framework, APC advocates continuous tuning of the process to achieve minimum variance control. Descriptions of this approach and discussion of the differences between APC and SPC are provided by a number of authors, including Box and Kramer [8], Macgregor [9,10], Macgregor, Hunter, and Harris [11], and Montgomery and others [12].

3. A third strategy advocates removing autocorrelation from the data and constructing a Shewhart chart (or an EWMA chart or a CUSUM chart) for the residuals; refer, for example, to Alwan and Roberts (1988).

In this paper, process, $X_t$, is considered an ARMA (1, 1) model, because most auto correlated manufacturing processes can be modeled by the popular first-order ARMA model [13].

As with the process dynamic model, the ARMA model can be represented in several forms. Here the state-space form is considered which will be used in the simulation modeling. The interested reader may refer to Box et al. [14].

for an introduction to state-space equations for ARMA models:

$$X_t = (1 - \phi_1 \mu_0 + \phi X_{t-1} + \epsilon_t + \theta \epsilon_{t-1}$$

where $X_t$ is the observation at time $t = 1, 2, \ldots$, $\epsilon_t$ is the random noise at time $t = 1, 2, \ldots$ assumed to be i.i.d. normal $(0, \sigma_\epsilon)$, $\phi$ is the autoregressive parameter, $\theta$ is the moving average parameter and $\mu_0$ is the nominal mean of the process. The ARMA parameters, $\phi$, $\theta$ and $\mu_0$ are assumed to be known.

The following Sections should be taken to build the model. Section 3.1 describes setting simulation initial data and running simulation model. Section 3.2 introduces gathering collected data and set appropriate time series model. Section 3.3 and 3.4 deals with setting control limit for data and identify the initial transient.

3.1 Set simulation initial data and run simulation model

First, time-series data on a key output statistic need to be collected. Typically this would be throughput for manufacturing systems and customer waiting time in service systems. The output data should be collected over a series of replications to provide a number of samples for each data point. The observation interval should be relatively short; for typical manufacturing and service system models a one hour interval is probably appropriate.

The length of each replication also needs to be determined. It is recommended that the run length is at least four times longer than the estimated length of the initial transient [3].

Generally, however, identification and estimation of ARMA models should be based on at least 50 and preferably 100 or more observations [3] and at least 60 data points are collected in each replication. An initial estimate of the
length of the initial transient could be obtained by simply inspecting a time-series of the output data to look for where the model appears to be in steady-state.

For running simulation model Arena software is applied that has more capability for running simulation model [15].

### 3.2 GATHERING COLLECTED DATA AND SETTING APPROPRIATE TIME SERIES MODEL

After running simulation model, formulation of partial autocorrelation function and sample autocorrelation function are programmed in Arena software with visual basic language to determine type of autocorrelated time series model. The partial auto correlation function is defined as follows [13]:

\[
 r_k = \frac{\sum_{t=1}^{N-k} (x_t - \bar{x})(x_{t+k} - \bar{x})}{\sum_{t=1}^{N} (x_t - \bar{x})^2}
\]

where \( r_k \) is partial autocorrelation at lag \( k \), \( N \) is number of data and \( \bar{x} \) is the average of data. Also sample autocorrelation function is described in Box & Jenkins [13]. After selecting appropriate time series model and setting parameters for this model, control limit is set for data.

As mentioned before, in this paper process, \( X_t \), is consider an ARMA(1, 1) model, because most auto correlated manufacturing processes can be modeled by the popular first-order ARMA model [13].

### 3.3 SETTING CONTROL LIMIT FOR DATA

SPC is traditionally applied to processes in which successive observations are assumed to be independent and identically distributed (i.i.d.). Unfortunately, the i.i.d. assumption is often violated in practice, and the presence of autocorrelation has a serious impact on the performance of the control charts. To deal with autocorrelated data, various charting techniques have been proposed. The residual-based chart or the special cause chart (SCC) is one of the most widely used methods [16, 17]. The key idea of the residual-based charts is to fit a time series model to subtract the autocorrelation and then to monitor the residuals. Assuming that the time series model is accurate, the residuals are statistically independent, and thus conventional control charts, such as the Shewhart, cumulative sum (CUSUM) or EWMA chart, can be applied to the residuals. The residual behavior of an autocorrelated process has gained extensive attention. Moskowitz et al. [17] studied the residual-based charting performance for ARMA (1, 1) process, and VanderWiel studied it for IMA (0, 1, 1) process. Hu and Roan [18] investigated the change patterns of the residuals for ARMA (1, 1) and ARMA (2, 1) processes. The relationship between the standard deviation, \( \sigma_x \), of the ARMA (1, 1) process, \( X_t \), and the standard deviation, \( \sigma_\varepsilon \), of the random noise, \( \varepsilon_t \), is known to be[19]:

\[
 \sigma^2_x = \frac{1 + \theta^2 - 2\phi\theta}{1 - \phi^2} \cdot \sigma^2_\varepsilon
\]

(3)

Here, the SCC is merely an individual chart for the random noise, \( \varepsilon_t \), i.e:

\[
 \varepsilon_t = X_t - (1 - \phi)\mu_0 - \phi X_{t-1} - \theta \varepsilon_{t-1}
\]

(4)

where \( \varepsilon_t = X_t - \mu_0 \); since \( \varepsilon_t \) is assumed to be an i.i.d. normal \( (0, \sigma_\varepsilon) \) random variable when the process is in-control. In this situation the control limits of the SCC chart are simply:

\[
 CL = \pm K \sigma_\varepsilon
\]

(5)

where \( K \) is a constant that is usually chosen to be 3 (see Montgomery [20]).
3.4 **IDENTIFY THE INITIAL TRANSIENT**

The final step is to view the plot of the control chart. This step is the same as Robinson method [3] during the initial transient the time-series data will be “out of control”. Once the model reaches steady-state, the data will be “in-control”. Bissell identifies a number of rules to determine whether a control chart is showing data that are out of control [21]:

- The time-series data violates an action limit (note that occasional violations, 1 in 1000, are to be expected for in-control data, and can be explained by Type I errors).
- Two consecutive values violate either the upper or the lower warning limit.
- Frequent values in relatively close succession that violate a warning limit.
- Persistent trend in the time-series data.
- A run of seven or more values on either side of the central line.
- Excessive zigzagging, with few points near to the central line and many near to the control limits.

The warm-up period for the model can be selected by identifying the point at which the time-series data is in-control and remains in-control.

4. **EXAMPLE FOR APPLICATION OF PROPOSED METHOD**

In order to implement the application of method, one simulation example is demonstrated. These data are used as output data to simulate an ARMA (1, 1) process.

Ten replications were performed with a run length of 1,000 hours. Statistics were collected on hourly throughput consisting of 100 observations, $X_t$, that correspond to an in-control process. In Figure 2, plot for the classical $3\sigma$ control limits for the SCC chart is showed, with $\pm 3\sigma = \pm 0.352$.

![Figure 2: Output analysis of simulation model with control limits](image-url)

As shown in Figure 2, if the process is assumed in-control, 3 points are out of control limits. So in this example 25 time unit is appropriate for warm-up period.
5. CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE STUDIES

In the previous related works, simulation output is supposed to be none correlated. But typically because of
simulation nature, output is autocorrelated and so these methods were not appropriate to determine warm-up period
and get not proper result. So, this paper studies warm-up period in discreet event simulation and develops algorithm
to determine the warm-up period with autocorrelated data. For doing this Box & Jenkins model is applied. One
example is given to apply the developed algorithm and showed that this algorithm how work in sample problem.

The following areas of research are recommended for future studies:
1. Other types of autocorrelated time series model such as ARIMA, AIMA and etc models can be
   considered in future studies.
2. Other types of control limits can be taken in the future research.
3. Some new studies are made to automation of warm-up period detection by applying some
   programming code in simulation software for determining optimized autocorolated model.

ACKNOWLEDGEMENTS

ABSTRACT

The paper addresses the problem of multi depot vehicle routing in order to minimize the delivery time of vehicle objective. Three hybrid heuristics are presented to solve multi-depot vehicle routing problem. Each hybrid heuristic combines elements from both constructive heuristic search and an improvement technique. The improvement techniques are deterministic, stochastic and simulated annealing (SA) methods. Experiments have been run on a number of randomly generated test problems of varying depots and customer sizes. Our heuristics are shown to outperform one of the best-known existing heuristic. Statistical tests of significance are performed to substantiate the claims of improvement.

1. INTRODUCTION

The vehicle routing problem (VRP) is a generic name referring to a class of combinatorial optimization problems in which customers are to be served by a number of vehicles. The vehicles leave the depot, serve customers in the network and on completion of their routes return to the depot. Each customer is described by a certain demand. Other information includes the coordination and distance between depot and customers and the capacity of the vehicles providing the service. In the other word, VRP involves the design of a set of routes for a fleet of vehicles, starting and ending at a depot and serving a number of customers with known demands. Each customer must be visited by one of these routes and the objective is to minimize the global cost of the set of routes [1]. The VRP has extensive variants, including the PVRP: periodic VRP in which the customers are served in a period of time rather than one day, the VRPPD: VRP with pickup and delivery in which the customers may both receive and send products, the VRPTW: VRP with time windows in which the vehicles must arrive at the customers before the latest arrival time, while arriving before the earliest arrival time results in waiting and so on [2]. A common point of the above versions is that they are all based on one depot. Thus, they can be regarded as single-depot VRPs. Although the single-depot VRPs have attracted so much attention, they are not suitable for some cases where a company has more than one depot. Due to this reason, this paper focuses on the single-depot and multi-depot VRP (MDVRP) in which more than one depot is considered. Because there are additional depots for storing the products, the decision makers also have to determine which customers are served by which depots, that is, the grouping problem prior to the routing and scheduling problems. Obviously, this type of problem is more challenging and sophisticated than the single-depot VRPs. Besides, the MDVRP is NP-hard, which means that an efficient algorithm to solve the problem to optimality is unavailable. Therefore, solving the problem by an exact algorithm is time consuming and computationally intractable. To deal with the problem efficiently and effectively, three probabilistic hybrid heuristics are developed in this paper.

This paper is organized as follows. Section 2 surveys on the relevant literature. Section 3 describes the hierarchy of decisions in the MDVRP. Section 4 discusses the principles of the algorithms used to solve the MDVRP. Section 5 compares the performance of the algorithms. Finally, Section 6 concludes the paper.

2. LITERATURE REVIEW

Over the last 30 years or so, the classical VRP has attended strongly in the literature. Comparatively, the number of research projects on the MDVRP is fewer. Tabu search heuristics for the MDVRP have been proposed by Renaud
et al. [3] and Cordeau et al. [4]. The recent paper deserves special attention as it describes a general heuristic that also solves periodic vehicle routing problems (PVRP) and periodic traveling salesman problems. Earlier, Chao et al. [5] proposed a record improvement heuristic for the MDVRP.

Ho et al. [2] developed two hybrid genetic algorithms (HGAs) for MDVRP. The major difference between the HGAs was the initial solutions. Pisinger and Ropke [6] presented a unified heuristic which is able to solve different variants of the vehicle routing problem. Crevier et al. [7] addressed an extension of the multi-depot vehicle routing problem that vehicles may be replenished at intermediate depots along their routes. Salhi and Sari [8] proposed a heuristic method with three levels to solve the MDVRP. The first level was the construction of an initial feasible solution. The second and the third levels were to improve the routes in each depot, that is, intra-depot and the routes in all depots, that is, inter-depot, respectively. Su [9] proposed a dynamic vehicle control and scheduling system to solve the MDVRP. All the control decisions were made according to the real time status of the system, such as the location, quantity, and due date of the demand. Wu et al. [10] studied the multi-depot location-routing problem (MDLRP), which is an extension of the MDVRP. The MDLRP was decomposed into the location-allocation problem and the VRP, and then they were solved sequentially and iteratively using the simulated annealing (SA). The major difference between the MDLRP and the MDVRP is that the former also determined the number and locations of depots. Giosa et al. [11] investigated the multi-depot VRPTW (MDVRPTW), which is also an extension of the MDVRP. The authors designed and compared six heuristics for assigning the customers to depots while using the same VRP heuristic for each depot. Similar to Wu et al. [10], Wasner and Zapfel [12] also studied the MDLRP for planning of parcel service. A heuristic method based on the local search with a series of feedback loops was developed to solve the problem separately. Nagy and Salhi [13] presented a number of heuristic methods to solve the single-depot VRPPD. The methods can be modified to tackle the multi-depot VRPPD (MDVRPPD).

Due to the complexity of the problem, solving the MDVRP to optimality is extremely time-consuming. To tackle the problem efficiently, all previous researchers preferred heuristic methods to exact algorithms. According to the above literature review, there are two common points among these proposed methodologies. First, the MDVRP was decomposed, and then the sub problems were solved sequentially and iteratively. Second, the heuristic methods consisted of two mechanisms: construction and improvement. The first mechanism generated initial feasible solutions, whereas the second mechanism modified the existing solutions to yield better results. However, it is found that none of the researchers have applied the probabilistic hybrid heuristics to solve the MDVRP. This is our primary motivation for writing this paper.

3. MULTI-DEPOT VEHICLE ROUTING PROBLEM

Consider a distribution company with multiple depots. The number and locations of the depots are predetermined. Each depot is large enough to store all the products ordered by the customers. A fleet of vehicles with limited capacity is used to transport the products from depots to customers. Each vehicle starts and finishes at the same depot. The location and demand of each customer is also known in advance. Each customer is visited by a vehicle exactly once. This practical distribution problem can be regarded as the MDVRP, in which there are three decisions as: 1) grouping: assigning customers to depots, 2) routing: assigning customers in each depot to routes and 3) scheduling: sequencing each route in every depot. The decision makers first need to cluster a set of customers to be served by the same depot, that is, the grouping problem. Then they have to assign customers of the same depot to several routes so that the vehicle capacity constraint is not violated. At last, the decision on delivery sequence of each route is made. Generally, the objective of the MDVRP is to minimize the total delivery distance or time spent in serving all customers. Shorter delivery time results in higher level of customer satisfaction.

Besides, the objective can also be the minimization of the number of vehicles required. Fewer vehicles imply that the total operation cost is reduced. No matter which type of objectives is defined, the ultimate goal of the MDVRP is to increase the efficiency of the delivery.

3.1. FORMULATION

The objective is to design the delivery routes from a depot to customers, i.e., to determine a sequence of customers on each vehicle route. Customer demands are deterministic and known. The time required to travel between customers including the depot is deterministic. All the vehicles have the same capacity. Each vehicle starts the travel from a depot and has to return to a depot in completion of services to customers. The notations and mathematical formulation are as follows:
Sets

- $I$: Set of all depots
- $J$: Set of all customers
- $K$: Set of all vehicles

Parameters

- $N$: Number of customers
- $C_{ij}$: Distance between point $i$ and $j$, $i, j \in I \cup J$
- $V_I$: Maximum throughput at depot $i$
- $d_j$: Demand of customer $j$
- $Q_k$: Capacity of vehicle (route) $k$

Decision variables

- $x_{ik}$: 1, if point $i$ immediately precedes point $j$ on route $k$ ($i, j \in I \cup J$); 0, otherwise.
- $z_j$: 1, if customer $j$ is allocated to depot $i$; 0 otherwise.
- $U_a$: auxiliary variable for sub-tour elimination constraints in route $k$.

Mathematical model:

\[
\begin{align*}
\text{Min} & \quad \sum_{i \in I} \sum_{j \in I \cup J} \sum_{k \in K} C_{ij} x_{ik} & (1) \\
\sum_{k \in K} x_{ik} & = 1, \quad j \in J & (2) \\
\sum_{k \in K} x_{jk} & = 1, \quad i \in I & (6) \\
\sum_{j \in J} d_j x_{jk} & \leq Q_k, \quad k \in K & (3) \\
\sum_{k \in K} x_{ik} - \sum_{k \in K} x_{jk} & = 0, \quad k \in K, i \in I \cup J & (5) \\
\sum_{j \in J} x_{jk} & \leq 1, \quad k \in K & (7) \\
\sum_{j \in J} z_j & \leq V_I, \quad i \in I & (7) \\
\sum_{i \in I} z_j & + \sum_{j \in J} (x_{ij} + x_{ji}) & \leq 1, \quad i \in I, j \in J, k \in K & (8) \\
x_{ij} & \in \{0,1\}, \quad i \in I, j \in J, k \in K & (9) \\
z_j & \in \{0,1\}, \quad i \in I, j \in J & (10) \\
U_a & \geq 0, \quad l \in J, k \in K & (11)
\end{align*}
\]
The objective function minimizes the total delivery distance. Eqs. (2) require that each customer be assigned to a single route. Eqs. (3) are the capacity constraint set for vehicles. Eqs. (4) are the new sub-tour elimination constraint set. Flow conservation constraints are expressed in (5). Constraints (6) assure that each route can be served at most once. Capacity constraints for the depots are given in (7). Constraints (8) specify that a customer can be assigned to a depot only if there is a route from that depot going through that customer. Constraint sets (9) and (10) are the binary requirements on the decision variables. The $u_a$'s auxiliary variables taking positive values are declared in (11).

4. SIMULATED ANNEALING

Since the third proposed hybrid heuristic benefits simulated annealing (SA) method in the improvement phase, following gives a short explanation of this method.

SA of Aarts and Korst [14] and Van Laarhoven and Aarts [15], a heuristic search method based on ideas drawn from statistical physics, has been found to be effective in many combinatorial optimization problems. The algorithm begins with a randomly generated initial point (the trial solution). This initial solution is the “current” solution. A neighbor (an adjacent point) of this current solution is then generated, following some predetermined neighbor-generating method. If the neighbor is found to be better than the current point, it (the neighbor) is unconditionally accepted as the new current point. On the other hand, if the neighbor is found to be worse, it is not rejected outright, but accepted with a certain probability. The algorithm proceeds by iterating a certain number of times over the transition from the current point to the adjacent point (which becomes the next current point). At the beginning of a SA run, the probability of accepting a worse point is kept high (thereby reducing the chance of the SA algorithm getting trapped in a local optimum). As the number of iteration increases, this probability is reduced according to a specific policy. It is customary to use a control parameter, called the temperature (analogous to the temperature of the physical process), to alter the probability of acceptance/rejection. Usually, the temperature is started at a high value and is gradually brought down according to a schedule known as the annealing (cooling) schedule. This annealing schedule determines how the probability of accepting a worse point decreases with time (iterations).

5. THE PROPOSED HYBRID HEURISTICS

Each hybrid heuristic methods combines elements from both constritive heuristic search and a improvement technique. The improvement techniques are deterministic, stochastic and simulated annealing methods. Now based on the above explanations, following contains three hybrid heuristic methods.

5.1. INITIALIZATION

The path representation is used to encode the solution of the MDVRP. The idea of the path representation is that the customers are listed in the order in which they are visited. For example, suppose that there are six customers numbered 1–6. If the path representation is (0 2 4 1 0 3 6 5 0), then two routes are required to serve all these six customers. In the first route, a vehicle starts from the depot, which is denoted as 0, travels to customers 2, 4, and finally customer 1. After that, the vehicle returns back to the depot. In the second route, the vehicle starts with customer 3, then customer 6, and finally customer 5. Similarly, the vehicle travels back to the depot after serving the customers. Note that each chromosome contains n links if there are n depots in the MDVRP. In the stage of initialization, there are three steps to generate a feasible initial solution. The first step is to assign customers to each of n links, that is, the grouping problem.

There are a number depots and customers and each customer must be assigned to one depot or link. Because the objective here is to minimize the total delivery time spent in distribution, customers are assigned to the nearest depot. For example, there are two depots, that is, $d_s$ and $d_a$ available in the MDVRP. Each customer, say $c_i$, should be assigned to a single depot exactly. The selection is based on the following calculation:

- If $D(c_i,d_s) < D(c_i,d_a)$, assign $c_i$ to $d_s$;
- If $D(c_i,d_s) > D(c_i,d_a)$, assign $c_i$ to $d_a$;
- If $D(c_i,d_s) = D(c_i,d_a)$, select the depot arbitrarily;

where $D(c_i,d) = \sqrt{(x_c - x_d)^2 + (y_c - y_d)^2}$.
represents the distance between customer i and depot k.

The second step is to assign customers in the same link to several routes using the Clarke and Wright [16] saving method. The saving regarded in this paper is the distance traveled by the vehicles to serve the customers. The method is to construct a saving matrix, $S(i, c, k)$, for every two customers in the same link first. Then, the customers with larger saving value are grouped in the same route while not violating the vehicle capacity constraint. We have

- **Saving matrix for Link 1:** $S(i, c, k) = D(d_i, c) + D(d_c, k) - D(d_i, c, k)$;
- **Saving matrix for Link 2:** $S(i, c, k) = D(d_i, c) + D(d_c, k) - D(c, k)$.

The third step is to solve the scheduling problem by the NNH [17]. The principle of the NNH is to start with the first customer randomly. Then the next customer is selected as close as possible to the previous one from those unselected customers to form the delivery sequence until all customers are selected.

### 5.2. IMPROVEMENT

Generally, the objective of the MDVRP is to minimize the total delivery distance or time spent in serving all customers. Shorter delivery time results in higher level of customer satisfaction. The corresponding objective function is represented as OB in all heuristics.

**Improvement M1**

1. For $i = 1$ to $n$ (number of customers) do
   - Randomly interchange any two customers belonging to the one route or two different routes in the solution obtained in the initialization step, find the OB of the modified schedule, and accept it as the current best solution if its OB is better, otherwise continue working with the original solution.
2. Use the output of the current solution as the final solution.

   The M1 may interchange the customers within the same route, that is, intra-route improvement or within the same depot, that is, intra-depot improvement. The M1 may also swap a customer from one route to another route, that is, inter-route improvement or from one depot to another depot, that is, inter-depot improvement. The type of improvements performed is dependent on the selection of customers in Step 1.

**Improvement M2**

Algorithm M2 attempts to improve upon M1 by deterministically accepting the adjacent solution if it is better than the current one, and accepting it probabilistically if it is not.

Here are the following steps:
1. For $i = 1$ to $n$ do
   - Randomly interchange any two customers belonging to the one route or two different routes in the solution obtained in the initialization step, find the OB of the modified schedule, and accept it as the current best solution if its OB is better, otherwise accept it with probability $e^{-\Delta/T}$, where $\Delta = OB(modified) - OB(original)$, and $T$ is a parameter of the algorithm that is held fixed at a predetermined value during the course of a run.
2. Use the output of the current solution as the final solution.

**Improvement M3**

This heuristic applies SA to improve upon the best solution obtained at any step of the algorithm.

The algorithm is described as follows:
1. For $i = 1$ to $n$ do
   a) Initialize Max-iterations, Temp-start.
      Set Count = 1, $T = Temp-start$.
      Let the best solution obtained in the initialization step be called the current solution, $x_0$.
      Compute OB($x_0$).
   b) Randomly generate a neighboring solution using either the interchange neighborhood, Forward Insertion Neighborhood or Backward Insertion Neighborhood (these neighborhoods are explained below). Let the neighboring solution be called the adjacent solution, $x_a$. Compute OB($x_a$).
   c) If $OB(x_a) < OB(x_i)$
      Then set $x_i = x_a$;
      Else
• Set $D = \text{OB}(x_i) - \text{OB}(x_j)$;
• Set $T = \text{Temp-start}/\log(1+\text{Count})$;
• With probability $e^{-\lambda/T}$ set $x_i = x_j$.

d) Increment Count by 1;
If Count $<$ Max-iterations, go to step b.

2. Use the output of the current solution as the final solution.

The annealing schedule used in step 1(c) of the above algorithm is due to Hajek [18]. The interchange neighborhood, by far the most popular scheme, is extremely simple: swap two randomly chosen customers in the sequence. Two other neighborhoods are something that Gupta and Smith [19] have introduced. In forward insertion neighborhood a customer is relocated further forward in the sequence and in backward insertion neighborhood a customer is relocated further backward in the sequence.

Three proposed methods are called by HM1, HM2 and HM3 respectively.

6. COMPUTATIONAL EXPERIMENTS

In this section, a computational study is carried out to compare the HM1, HM2, HM3 and the best assignment algorithm developed by Giosa et al. [11]. The performance of methods is evaluated using six randomly generated examples: 20-customer, 50-customer, 100-customer and 200-customer MDVRPs, in each of which there are two, three or five depots available. For each problem size, 10 independent problem instances were created. In Tables 1–3 each test suite comprises 10 independent instances. The OB values appearing in Tables are averages of 10 OB obtained from as many problem instances. The results indicate that HM1 and HM2 produce solutions of a better quality than assignment algorithm cited above for all problem sizes except two cases. Heuristic HM3 is vastly superior to HM1 or HM2 and outperforms assignment algorithm in all cases.

Now the hypothesis is tested that the population corresponding to the differences has mean $\mu$ zero. Specifically, the (null) hypothesis $\mu = 0$ is tested against the alternative $\mu > 0$. It is assumed that the OB difference is a Normal variable, and choose the significance level $\alpha = 0.05$. If the hypothesis is true, the random variable $T = (\bar{X}_1 - \bar{X}_2)/\sqrt{\left(\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2}\right)}$ has a $t$ distribution with:

$$\nu = \left(\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2}\right) / \left(\frac{S_1^2}{n_1 - 1} + \frac{S_2^2}{n_2 - 1}\right)$$

degrees of freedom. The critical value of $c$ is obtained from the relation

$$\text{Prob}(T > c) = \alpha = 0.05.$$ For example, the first entry in Table 3 corresponds to the sample size $n_1 = 10^2$, $\mu_0 = 0$, sample mean for assignment algorithm and HM3 are $\bar{X}_1 = 80.31$ and $\bar{X}_2 = 77.34$ respectively. Sample standard deviation for assignment algorithm and HM3 are $S_1 = 1.10$ and $S_2 = 2.12$ respectively. Since $t = 3.94 > t = 1.77$, it is concluded that the difference is statistically significant. Table 3 displays HM3 outperforms assignment algorithm in all cases. Also in all cases differences are significant.

7. CONCLUSION

Routing and scheduling of deliveries are two crucial operational decisions in logistics distribution management. Better routing and scheduling can result in shorter delivery distance, or time, and thus, higher level of efficiency and lower delivery cost can be achieved. The VRP is used prevalently to aid the planning of these two decisions. However, the VRP is not applicable when a logistics distribution company has multiple depots. In this paper, the MDVRP was studied because the number of depots is not limited to one in many real-world situations. Besides routing and scheduling, the grouping problem is also considered in the MDVRP. Because the MDVRP integrates three hard optimization problems, three improvement techniques is introduced to challenge it. Nearest depot method, Clarke and Wright saving method and NNH for grouping, routing and scheduling of customers are used in the initial solution and improve the initial solution by three approaches. A computational study was carried out to compare HM1, HM2, HM3 and one of the strong assignment algorithm method developed by Giosa et al. Experimental results show that HM1 and HM2 outperform assignment algorithm in the most cases but all differences are not significant. HM3 completely outperforms assignment algorithm and also all differences are significant.

ABSTRACT

We consider a parts input problem in a flexible production system consists of 2 production lines that are an Up-Stream production line and a Down-Stream production line. The Up-Stream production line processes incoming materials by several machine tools and after processing them, delivers the parts to the Down-Stream production line via buffers. In this paper, the parts input rules to the Up-Stream production line is based on the observation of the parts line-up situation on buffers. By using the parts observation, a real-time control of parts input by pattern recognition called Real-Time Parts Input by Pattern Recognition System (RT-PIPS) is proposed. The pattern recognition consists of pattern classification process and pattern identification process. Simulations of virtual production systems have been carried out to verify that RT-PIPS is useful in real-time parts input control.

1. INTRODUCTION

One of the flexible production systems that produce multiple type parts is Flexible Transfer Lines (FTLs). Often, many FTLs operate under the Just In Time (JIT) [1-3] production policy in conditions where each of the FTLs are linked together. The conceptual JIT production policy is defined as “the basis of the Toyota production system in which the right parts are needed in the assembly line at the time they are needed, and only in the amount needed” to achieve “the absolute elimination of waste”. A JIT production system is a pull production system, in which the most well known is called the Kanban system [4]. A Down-Stream production line informs the Up-Stream production line of the needed types and amount of parts beforehand. For instance, a parent company makes a weekly pre-decided production schedule of certain parts (such as 3000 pieces of part A, 2500 pieces of part B etc.), in advance. Normally, the Up-Stream production line will schedule the part input to the production line based on the pre-decided production schedule. Pull production systems are most successful in production environments with stable demand and lead times [5, 6]. Unfortunately, when a company experiences wide variations in supply and demand from customers, the pre-decided production schedule cannot be maintained and is liable to change on the current day. In addition, an adaptive type of pull production system was proposed to monitors the actual inventory levels and adjusts the number of Kanban by releasing and capturing extra Kanban based on customer demands [7]. Moreover, Gold [8] studied a sophisticated batch service system in a push and pull manufacturing environment by using embedded Markov chain techniques.

Most of these studies only focus on a single stage system or single-product Kanban system. A mathematical method and simulation approach offline pre-decided production scheduling has also been proposed [9, 10]. Furthermore, a reactive JIT ordering system [11] for multi-stage production systems with unstable changes in demand was also proposed. However, a pre-decided production schedule is not effective if the demands from the preceding process are different from the actual schedule. In this paper, we propose a real time control of parts input control by pattern recognition called Real Time Parts Input by Pattern Recognition System (RT-PIPS). RT-PIPS observe the parts line-up situation in real-time and uses pattern recognition methods to analogize the situation. The pattern recognition method consists of two processes that are the pattern classification and the pattern identification process. In the pattern classification, the number of Out-pattern is reduced and in the pattern identification, by analogizing the situation with the pattern recognition, the most similar pattern to the parts on buffers (BUFF) can be determined. This pattern is collated with IF-THEN to acquire a rule that decides the next parts input to the bay of the Up-Stream

Flexible Automation and Intelligent Manufacturing, FAIM2009, Teesside, UK

production line. In other words, the parts input can be decided by collating the results from pattern recognition analogical process to acquire rules for parts input. It is alike a feedback process of control system.

We adopt RT-PIPS to a virtual production system to verify that it will not negatively affect the Down-Stream production line even though the actual demands from the Down-Stream production line are different from the pre-decided schedule.

2. MODEL OF PRODUCTION SYSTEM

The production model that we consider in this paper is shown in Figure 1. This model considers a production system that consists of two types of production lines. One of the two types of the production lines is an Up-Stream production line that consists of multiple machine tools lined serially. The other is a Down-Stream production line that consists of many assembly processes. The parts are input one by one to the bay of the Up-Stream line by using the *One by One Part Input Method* [12]. The input parts are machined by its sequence by the machine tools. The parts line-up situations on the buffer (BUFF) are monitored in real-time. To realize the real-time control of parts input, a real-time control system that is based on pattern recognition method to decide the parts input to the bay of Up-Stream production line is used.

A set of Out-pattern is created randomly from the parts line-up combinations as identifiable patterns. Then, the identifiable patterns are recognized by adopting a pattern identification process. The pattern identification process is divided into two categories that are a Sum Square Method (S²M) and a Rank Replacement Method (R²M) to analogize the Out-patterns. The analogical result is then collated with parts input decisions rules to decide the next parts input rules. In the paper, we adopt IF-THEN rules as the parts input rules.

2.1. DIFFICULTIES OF DECIDING PARTS INPUT RULES

In the case where two production lines are linked and operated as a single production line, it is difficult to implement a pre-decided production schedule due to the difference between parts demands from the actual pre-decided production schedule. Solving this problem necessitates a real-time control of parts input to the bay of the Up-Stream production line during operation. However, it is quite difficult to perform a real-time control because during performing a real-time control of parts input in the flexible production system, two points of difficulties have to be settled down. The first difficulty is that the parts line-up situations on the BUFF consist of tremendous combinations, resulting in the creation of tremendous IF-THEN rules. For instance, a flexible production system that
processes \( n \) types of parts with the capacity of parts that can be lined up on the BUFF as \( b \) pieces, then it will have \((b+1)^n\) combinations.

The second difficulty relates to the constant search for accurate IF-THEN rules. From the parts input in the Up-Stream production line to the parts transferred to the BUFF, there are time lags exist between these periods. Furthermore, many parts are discharged from the production line occasionally due to machining defects, which leads to unclear situations of parts that line-up on the BUFF. Because of this reasons, the relationship between the parts situations on the BUFF and the parts input in the Up-Stream production line no longer associates as a one-to-one correspondence. It means there is no guarantee that each IF-part will correspond with one THEN-part. In the paper, both of the difficulties will be solved by our proposed RT-PIPS. The later sections of the paper describe details of the proposed RT-PIPS.

3. RULES OF ACQUISITION BY RT-PIPS

3.1 PRE-DECIDED PARTS INPUT SEQUENCE

In the paper, in order to reduce the tremendous combinations of the IF-THEN rules, we use the Out-pattern concept where smaller numbers rather than the numbers of parts line-up situations on the BUFF \((b+1)^n\) are adopted. It means that by expressing the parts line-up situations on the BUFF with the Out-pattern concept, the parts line-up situation can be limited to only \( m \) pieces of combinations, where \( m \ll (b+1)^n \). Each \( m \) pieces of the parts line-up situations are expressed by Out-pattern \( O_p(m) \).

In other words, the Out-patterns are configured as an alternative expression of the tremendous parts situations that are lined up on the BUFF. \( m \) pieces of Out-pattern \( O_p(m) \) are compared with the actual parts line-up situation as shown in Figure 2 by the pattern recognition. The pattern recognition method involves 2 processes. One is the pattern classification process. The pattern classification process is carried out of-line. The pattern classification process consist of random creation of Out-pattern set and pattern classification where the set of Out-pattern is classified based on its geometrical pattern into several Out-pattern groups. The Out-pattern groups are kept as database and is used during the analogy process of pattern identification process. The other process is the pattern identification process that is an analogy process where the Out-pattern groups are analogized on-line with the actual parts line-up situations on BUFF. We create the Out-pattern set to reduce the tremendous combinations of parts line-up situations. The Out-pattern set is then classified by the pattern classification into several Out-pattern groups.

![Figure 2 Pattern recognition of RT-PIPS](image-url)
3.2 CREATION OF OUT-PATTERN SET

In the paper, we create the Out-pattern set to reduce the tremendous combinations of parts line-up situations. TheOut-pattern set is then classified by the pattern classification into several Out-pattern groups. In the proposed RT-PIPS, in order to acquire the parts input rules by IF-THEN rules, the IF-part of the parts input rules are carried out by using the Out-pattern concept. Out-pattern is a concept of substitution of the actual parts line-up situation. In other words, the Out-pattern represents the pattern of the situation. Since the combinations of parts line-up are extremely tremendous, mathematically it is almost impossible to define the relations of the parts line-up situations and the parts input rules by mathematical formulation. So, the Out-pattern is taken as an alternative of the mathematical solutions. The creation of Out-pattern is done by generating random numbers of the product types in the FTL. The maximum BUFF size $b_{\text{max}}$ is given as a maximum number of each type $n$ of parts that can be line-up on the BUFF. By randomizing the numbers of all types of parts, the parts combinations ($PC$) on the BUFF can be determined.

$$PC = (b_{\text{max}} + 1)^n$$  \hspace{1cm} (1)

The Out-pattern for part $Op_n$ is generated randomly to the maximum BUFF size of each type of part as,

$$Op_n = \text{rand}[1,2,\ldots,b_{\text{max}}]$$  \hspace{1cm} (2)

where $n$ is the number parts types on the BUFF. The Out-pattern $O_p(m)$ is defined by the following equation,

$$O_p(m) = \{O_{p_1}, O_{p_2}, \ldots, O_{p_n}\}$$  \hspace{1cm} (3)

Then, the Out-pattern set is created by,

$$O_{\text{set}} = \{O_p(1), O_p(2), \ldots, O_p(m)\}$$  \hspace{1cm} (4)

where $m$ pieces of Out-pattern $O_p(m)$ which are far less than the actual parts combination numbers $(b+1)^n$. By using the Out-pattern, RT-PIPS describes the parts input rules as follows: the Out-pattern concept for the IF-part rules and parts input for the THEN-part rules. Furthermore, for each part that actually line-up on the BUFF, one Out-pattern corresponds to more than one possible parts input or THEN-part rule.

3.3 PATTERN CLASSIFICATION

The pattern classification process is to classify the elements of the Out-pattern set $O_{\text{set}}$ by its geometrical patterns into several specified groups as Out-pattern groups. In the paper the Out-patterns can be classify to 5 types Out-pattern groups as shown in Figure 3(a)~(e), that are the straight pattern, stair pattern, convex pattern, concave pattern and multi-concave pattern. By classifying these types of Out-pattern, the number of Out-pattern that should be analogized during the pattern identification process can be reduced far less than the tremendous numbers of parts line-up combinations. In addition, it can reduce the analogy process time of pattern identification process because only the associated Out-pattern that are classified into the specified groups will be analogized with the actual parts line-up. This means that the number of the Out-pattern $O_p(m)$ can be reduced to less than $m$ pieces. The Out-pattern group $O_{p\text{-group}}$ is expressed by the following equation.

$$O_{p\text{-group}} = \begin{bmatrix}
O_{p_{1,1}} & O_{p_{1,2}} & \cdots & \cdots \\
O_{p_{2,1}} & O_{p_{2,2}} & \cdots & \cdots \\
O_{p_{3,1}} & O_{p_{3,2}} & \cdots & \cdots \\
O_{p_{4,1}} & O_{p_{4,2}} & \cdots & \cdots \\
O_{p_{5,1}} & O_{p_{5,2}} & O_{p_{5,3}} & \cdots \\
O_{p_{6,1}} & O_{p_{6,2}} & O_{p_{6,3}} & \cdots \\
\end{bmatrix}$$  \hspace{1cm} (5)

Here, the elements of the Out-pattern groups are divided to 5 groups. Each row of the $O_{p\text{-group}}$ represents one group. The hyphens of element in the group express in which group the Out-pattern belongs to the number of the Out-pattern. Each group in the Out-pattern groups corresponds to each pattern in Figure 3(a)~5(e). A pattern classification is used before the pattern identification is done. The pattern identification process is an analogical process to compare the classified Out-pattern and the actual parts line-up situation on the BUFF. By analogizing the Out-pattern, the most similar Out-pattern can be determined.
3.4 Algorithm of RT-PIPS

In RT-PIPS, the actual parts situations that line-up on the BUFF are defined as facts that collate with the IF-part rules of the Out-pattern concept. The algorithm of RT-PIPS is done as follows.

**STEP1**: Calculate the number of parts situations Num ($P_n$) of each part $P_n$ and generate the set of parts situations numbers $S_{fact}$.

**STEP2**: Randomly create a set of Out-patterns $O_{set}$.

**STEP3**: Classify the prepared Out-pattern set by its pattern into Out-pattern groups $O_{p-group}$.

**STEP4**: Analogize between each element of $O_{p-group}$ and $S_{fact}$. Select the Out-pattern that is the most similar to the $S_{fact}$ as $O_p(M)$.

**STEP5**: Compare $O_p(M)$ and the THEN- rules and select all the parts input candidates that have the same rules. Set the candidates as $P_q$.

**STEP6**: Randomly select one part $P_{q1}$ from the overall $P_q$ as the input part.

3.5 Parts Input Rules

The THEN-part of the parts input rules describes how each Out-pattern is collated with the parts that will be input to the bay of the Up-Stream production lines. RT-PIPS selects the c pieces of the input part candidates as $I_c$ based on 5 standards as shown in Figure 4. The 5 standards indicate the priority of the input part which is judged based on the parts situations on the BUFF. Figure 4(a) ~ (e) illustrates the examples of these 5 standards respectively. In every figure, $d=d'=2$ and $P_1$~$P_{10}$ are the situations of the part line-up on the BUFF. Figure 4(a) shows a condition of [STANDARD1] where there are no parts lined up on the BUFF. In this case, each part $P_1$~$P_{10}$ can be selected as elements of $I_c$. Similarly, Figure 4(b) shows the condition of [STANDARD2]. In this case, since the difference between the desired $Opt(n)$ and the number of parts lined up on the BUFF are 2 pieces, part $P_2$ and $P_{10}$ can be selected as elements of $I_c$. Next, Figure 4(c) shows the condition of [STANDARD3] where part $P_2$, $P_3$, $P_8$ and $P_{10}$ are selected as elements of $I_c$ because these kinds of parts which are being lined up on the BUFF have not achieved the desired $Opt(n)$. Figure 4(d) shows the condition of [STANDARD4]. In this case, the difference between parts that are lined up on the BUFF and $Opt(n)$ which are less than 2 pieces can be selected as elements of $I_c$, i.e., $P_1$, $P_3$, $P_6$, $P_8$, $P_9$ and $P_{10}$. Lastly, Figure 4(e) shows the condition of [STANDARD5], where all parts can be selected as parts input candidate $I_c$. 

![Pattern Classification](image-url)
4. ANALOGY PROCESS WITH PATTERN IDENTIFICATION

The pattern identification process is to analogize the classified Out-pattern and the actual parts line-up situation on the BUFF to determine the most similar Out-pattern.

4.1 SUM SQUARE METHOD (S²M)

The smallest value of sum square of the different between the Out-pattern and the parts line-up situation on the BUFF is selected as the analogical result. The detail of the procedure is as follows:

**STEP1:** Calculate the number of the actual each parts line-up situation on the BUFF.

\[ P_i = \{p_{i1}, p_{i2}, \ldots, p_{in}\} \quad (6) \]

**STEP2:** Prepare a set of Out-pattern to be analogized with the parts line-up situation by generates randomly from the total number of combinations from \( P_i \).

\[ \text{Out}_{si} = \{O_{s1}, O_{s2}, \ldots, O_{sn}\} \quad (7) \]

**STEP3:** Subtract between the number of actual parts line-up and the Out-pattern.

**STEP4:** By using the following equation, the sum square of each parts can be calculated.

\[ X = \sum_{i=1}^{n} \left( p_i - O_{si} \right)^2 \quad (8) \]

**STEP5:** Select the smallest number of the calculated S²M as the most similar Out-pattern.
4.2 RANK REPLACEMENT METHOD (R²M)

The number of each type of the actual parts line-up on BUFF and the Out-pattern is ranked according to the smallest rank by a sorting and assimilation process of Out-pattern rank. The sorting process is as follows.

**STEP1:** List all the types of parts line-up on BUFF.

**STEP2:** Sort each type of the parts line-up on BUFF following the rank of the less number.

**STEP3:** Replace the rank of parts in Sorting-BUFF and number them as Sorting BUFF.

**STEP4:** List all the types of parts of Out-pattern and sort each type of the Out-pattern following the rank of the less number.

**STEP5:** Replace the rank of parts in Out-pattern and number them as Sorting Out-pattern.

The assimilation process is to re-rank the ranking of Sorting Out-pattern as follows:

**STEP1:** Assimilate between the new replaced S-BUFF and the new replaced Sorting Out-pattern.

**STEP2:** Change the rank of parts in Sorting Out-pattern to the same rank of the parts in Sorting-BUFF. Each time the rank is changed, one will be counted.

**STEP3:** The less counted Sorting Out-pattern is decided as the most similar Out-pattern to the parts line-up.

5. SIMULATIONS

We constructed a virtual production system and ran a simulation program. The developed RT-PIPS is applied once every 15 minutes to the virtual production system. The virtual production system consisted of a flexible production system that produced 10 types of different parts P₁, P₂, ..., P₁₀. The production ratios of the pre-decided production schedule of each part were set as, P₁ : P₂ : ... : P₁₀ = 3 : 6 : 4 : 3 : 5 : 2 : 3 : 3 : 4 : 6, respectively. In the virtual production system, the production periods were 40 hours. In order to generate a production system that was different from the pre-decided production schedule, the parts input orders were changed as the following condition.

<CONDITION-1> The parts pick-up by the Down-Stream production line is not changed from the pre-decided schedule.

<CONDITION-2> The parts pick-up by the Down-Stream production line is not so different from the pre-decided schedule.

<CONDITION-3> The parts pick-up by the Down-Stream production line is largely different from the pre-decided schedule.

These parts pick-up conditions are applied to check the effectiveness of the proposed method. The productivity of parts that are input to the Up-Stream production line by S²M and R²M are shown as Table 1 and Table 2. RT-PIPS demonstrates that although the parts pick up rules were changed; the decision of parts input can be done effectively by S²M rather than R²M.

6. CONCLUSIONS

We described the development of real-time control of parts input based on the JIT production policy by pattern recognition method. RT-PIPS can maintain stable production yields even though the production demands from the Down-Stream production line are different from the pre-decided production schedule. This means RT-PIPS that uses the Out-pattern concept collated to the IF-THEN rules is efficiently implemented.

Quick scan of the production system for disturbances

Paulina Golinska*, Marek Fertsch, Pawel Pawlewski

Faculty of Computing and Management
Poznan University of Technology
Poznan, 60-965, Poland

ABSTRACT

In European automotive industry very often a number of different not compatible information systems is used within one company. Due to a big number of information coming from production system to production database regarding production flow, the people responsible for production planning and control are overloaded with information. The production database is not appropriate analyzed and disturbances are not identified. An approach for production system observation is needed in order to identify when disturbances appear. The aim of the paper is to propose an approach for quick scan of the production system in order to identify disturbances in production flow.

1. European Automotive Producer-Main Characteristics

Production system typical for European automotive industry is a mixture of the traditional mass production features in the departments responsible for pre-treatment (D1,D2) and lean [1,2] concept in the area of the final assembly (D3). The production process can be divided into three technological phases: body welding, painting, final assembly. The simplified schema of production system is presented at Figure 1.

The production system is characterized by high stability understand as [3]:
- steady production plans
- Master Production Schedule (MPS) is prepared many weeks in advanced
- high similarity of production routines
- high similarity of product structure (BOM), however they may differ in number of specific attributes like for example color.

The manufacturer in order to protect the stability of production system and to achieve the gains of the economy of scale combine two policies by production planning, as followed: build-to-order and build-to-forecast.

* Corresponding author: Tel.: (0048) 6187-50446; Fax: (0048) 61665-3375; E-mail: paulina.golinska@put.poznan.pl
As researches conducted in the framework of the program “3DayCar” [4] had showed in European automotive industry forecast of customer demand regarding volume and item specification is prepared many months in advance in order to figure out an attractive product mix for assembly plant balancing. Actual customer orders that are received are either fitted into the plan laid out by the production programmed months ahead, or the forecast orders in the system are amended to customer requirements. In European automotive industry production scheduling is prepared 2-3 weeks before production starts. Order scheduling, which are picked from the order bank and assigns to production weeks at the different plants. The scheduled orders for a build week are re-shuffled into a sequence of build orders for the assembly plants. In any case, only after the orders are sequenced, do suppliers actually receive their final call-off of what is required, as only then it is actually defined what parts will be needed [4]. Sequenced orders are sent to the body shop (welding department). In case most of the manufacturers the paint shop is the bottleneck of the production process so, after the body shop in order to achieve efficiency in the paint shop bodies are accumulated to be sprayed in the same color. The initial production sequence is distorted and becomes unpredictable for all subsequent operations. After paint, the cars are generally re-shuffled again before they are sent on the assembly department, to ensure the mix of cars needed for the line balancing activities. The line balancing approach leads to need for a precise control of sequencing and quick response in situation when real production sequence is disturbed and differs from assumed plans. At the same time in case of automotive industry where Just-in-Time deliveries are common business practice changes that appear in Master Production Schedule results in problems with on-time customer fulfillment. Changes in Master Production Schedules (MPS) result in due-date changes in open orders, quantity and timing for planned order of end products. Mentioned above changes are being translated into gross requirements changes for components and timing of their delivery and it effects in situation that materials needed for a particular order may not be available particularly when there is an increased in ordered quantity and shorten due date.

Number of researches that has been conducted in automotive industry regarding the improvement of the performance concentrate mainly on material management within supply chain and integration of planning activities [ISOMA 4,5,6,7]. There is a research gap for evaluation of the influence that the disturbances have on production system. The following research project has show that there is a need to elaborate a set of simply method of production system monitoring in order to easily evaluate the sequencing activities and identify potential serious disturbances that negative affects the ability to fulfill customer’s orders on time.

2. DISTURBANCES IN PRODUCTION SYSTEM

2.1. SOURCES OF DISTURBANCES

The manufacturing system is treated as a complex entity combining technological-, social-, economics subsystems and being influenced by business environment [7]. The potential sources of uncertainty in manufacturing system presents Figure 2.

![Figure 2: Sources of uncertainty in manufacturing system, modified from [8]](image)

Inputs to manufacturing system include materials, energy, and information. The inputs are being transformed into products for customer. The value adding processes in manufacturing system creates incomes for company. The
macroeconomic climate may cause the shifts in business environment which influence inputs. Manufacturing system is dynamic and contains of materials, machines and tooling, people. The outputs of manufacturing system are mainly finished goods and semi-finished goods which are being offered to customer. Many of manufacturing companies base their production plans both on due-date customer orders and demand forecast. Shifts in macroeconomics conditions might influence the veracity of forecast and may lead to serious company financial problem, freezing resources in stocks that are not required by clients.

The uncertainty conditions combined with complexity of production system increase the risk of disturbance appearance. Disturbance can be defined as an unexpected and unplanned event, which causes the deviation between planned Master Production Schedule MPS and real production flow (production sequence) within production system. The deviation between initial planned and real production sequence resulting from intentional planner activities (e.g. change of initial order priority) won’t be treated as a disturbance. Disturbances in production system can differ a lot: e.g. breakdown of machines, serious delay in deliveries, workers absence. The disturbances can be classified based on two criteria:

1. source of disturbance
2. the effect it has on production system.

Taking in consideration the first criteria the following types of disturbances, as presented on Figure 3 can be defined.

Based on the second criteria the following types of disturbances can be identified [10]:

1. production control goal disturbances
2. production capacity disturbances
3. input disturbances
4. information flow disturbances.

The main goal of production control is production process execution according to the planned MPS. The disturbances of production control function goal are any deviations in the initial MPS execution appearing at independent demand level caused by changes in customer demand or customer’s order due dates. The production resources disturbances are any variations in initial MPS execution caused by limited availability of production capacities (machines, tooling, workforce). The input disturbances are any variations in initial MPS execution appearing at dependent demand level caused by shortages of raw materials. The input disturbances are any variations in initial MPS execution appearing at dependent demand level caused by inappropriate information and data on technology: e.g. not updated Bill of Material, invalid data on maintenances, lead times, inventory levels.
Table 1: Level of particular disturbances types appearance

<table>

</tr>
</tbody>
</table>

Due to the fact that production plans (and following them MPS) in European automotive industry are prepared many weeks in advance, it can be assumed that the demand is deterministic, so only disturbances appearing at MRP level will be taken into consideration in the quick scan approach.

3. Quick Scan Approach

3.1 Approach Presentation

The main value adding process is generated by final assembly (D3). All supplies of components are supposed to arrive at final assembly department in the required sequence due to the fact that there are usually no buffers. All deliveries of raw materials and components for final assembly are based on just-in-time basis, so any changes in order sequence results in problems with on-time deliveries of components, what seriously disturbs the MPS execution. Due complexity of the production systems in the automotive industry, there are problems to identify the sources of disturbances. On the basis of the case study and the literature review, the following approach for quick scan based on few simple indicators is proposed.

The production system in automotive industry is monitored usually by number of scanners that register the data from bar codes/GS1 codes plugged to any car body at the beginning of production process. The places where scanners are located can be called production control points (PCP). Number of PCPs differs among particular manufactures. The data from PCPs is sent in real time to production databases. The structure of data depends on particular company. It can be assumed that the minimal requirements for data needed to apply quick scan approach are (Figure 5):

- Production Order Identification Number (POIN)
- PCP identification code
- Date
- Time when particular POIN passes through particular PCP

Table 2: Simplified structure of database

<table>
<thead>
<tr>
<th>Production sequence /PCP</th>
<th>PCP 1</th>
<th>PCP 2</th>
<th>PCP …</th>
<th>PCP N</th>
</tr>
</thead>
<tbody>
<tr>
<td>POIN 1</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
</tr>
<tr>
<td>POIN 2</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
</tr>
<tr>
<td>…</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
</tr>
<tr>
<td>POIN N</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
<td>Date, Time</td>
</tr>
</tbody>
</table>

The quick scan approach is based on following indicators:

- Production flow cycle indicator $XY_{Long}$ is counted as a sum of time windows between moments when analyzed Production Order Identification Number (POIN) passes through following production control points PCPs (equation 1). The time when POIN enters the production system at PCP1 is counted as 0 ($t_{pcp1} = 0$):
Quick scan of production system for disturbances

\[ \text{XY Long} = \sum_{i=1}^{n} t_{pcpi} \]  \hspace{1cm} (1)

- For block of \( k \) number of POINs the indicator is counted as (equation 2):

\[ \text{XYLong}_{\text{set}} = \frac{1}{k} \sum_{k}^{n} \sum_{i=1}^{n} t_{pcpi} \]  \hspace{1cm} (2)

In order to define the typical and critical values of production flow cycle indicator for a block of POINs on basis of long time observation of non-disturbed POINs (with the same key features as analyzed block) the “ideal” values are counted \( \text{XYLong}_{\text{setID}} \).

- Sequence dispersion range (SDR)- measured for block of POIN as a difference between maximum order identification number in defined block and minimum identification number observed at chosen production control point (equation 3).

\[ \text{SDR} = (\text{POIN max} - \text{POIN min}) \]  \hspace{1cm} (3)

The values of SDR indicators shows how defined at MPS block of POINs has been distorted by appearance of number of POINs belonging to the other blocks of orders.

- The overall production sequence quality presents the number \( k \) of POIN in analyzed block to SDR at observed production control point for example if there was “\( k \)” POIN and the SDR equals to “\( k \)” the quality of operations management regarding sequencing will be 100%. The value of this indicator is counted as following (equation 4)

\[ \text{OPSQ} = \frac{k}{\text{SDR}} \times 100\% \]  \hspace{1cm} (4)

The low value of OPQS indicator informs about serious disturbance in production flow for analyzed block. On the basis of proposed indicators it is possible to monitor production flow and to identify when serious disturbances appear and regulatory activities are needed.

2.2. THE METHOD

The quick scan approach follows mentioned below steps:
1. Define the block of orders
2. Count the OPSQ indicator value
3. Evaluate the critical value of OPSQ indicator
4. If the value of OPSQ for defined block falls below critical value then analyze the \( \text{XYLong}_{\text{set}} \) at this PCP
5. Identify the type of disturbances

<table>
<thead>
<tr>
<th>Effects caused in production system by uncertainty</th>

<td>Breakdown of information systems, breakdowns of electricity supplies,</td>
</tr>
</tbody>
</table>
moters’ breakdown at the joint part of the production process

**Input disturbances**
- Non standard material requirements
- Non-standard supply lead times, poor quality, lack of needed components

**Information flow disturbances**
- Invalid production data (mainly invalid BOM)
- Changes in design of product, Non-standard design

### 3.2 Numerical Example

The numerical example presents the application of proposed quick scan approach. For the defined block of 15 orders the OPSQ indicator is calculated (Figure 6). The PCPs taken in consideration are:

- MPS-system entry the sequence is equal to initial MPS
- B1, B2- body shop (1) entry and (2) exit
- P1, P2- paint shop (1) entry and (2) exit
- A1, A2- final assembly (1) entry and (2) exit
- FC- final control

<th>W1</th>
<th>W2</th>
<th>P1</th>
<th>P2</th>
<th>A1</th>
<th>A2</th>
<th>FC</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>100,00%</td>
<td>63,93%</td>
<td>42,05%</td>
<td>37,04%</td>
<td>46,35%</td>
<td>47,47%</td>
<td>47,95%</td>
<td>60,36%</td>
</tr>
<tr>
<td>Tolerance 25%</td>
<td>0,00%</td>
<td>15,98%</td>
<td>10,51%</td>
<td>9,26%</td>
<td>11,59%</td>
<td>11,87%</td>
<td>11,97%</td>
<td>15,09%</td>
</tr>
<tr>
<td>critical value</td>
<td>100,00%</td>
<td>47,95%</td>
<td>31,53%</td>
<td>27,78%</td>
<td>34,76%</td>
<td>35,60%</td>
<td>35,91%</td>
<td>45,27%</td>
</tr>
</tbody>
</table>

The value of OPSQ indicator is equal 100% when production flow is not disturbed. For analyzed block (Table 4) it can be observed that the flow of production is seriously disturbed (below critical value Table 5) at body shop and paint shop. At final assembly department the production sequence (production flow) finally is undisturbed but at the end of production process again the sequence is extremely disturbed (below 5% of initial sequence in MPS is kept).

Following the described in Section 3.1 procedure if the value of OPSQ for defined block falls below critical value then the analysis of indicator the XYLong_set_av at this PCP is needed.
As presented at Figure 4 the low values of OPSQ at PCP from B1 to P1 are not followed by increase of XYLong indicator over critical value. On based of Table 3 it can be assumed that production sequence is disturbed by:

1.a machines’ breakdown at the separate production process part  
2.a non standard material requirements  
3.a non-standard supply lead times,  
4.a poor quality,  
5.a lack of needed components  
6.a invalid BOM .  

The disturbances caused by non-standard production can be eliminated (2a-3a) due to the block size. According to analyzed company organizational rules non-standard production block of orders cannot be bigger than 6 POINs. In case of poor quality (4a)at this production phases the orders have to be re-process so production flow indicator would increase. Invalid BOM (6a) disturbs the production at final assembly phase not at body and paint shop. The only possible causes of deviations between planned sequence are: machines’ breakdown at the separate production process part and lack of needed components. In order to fully identified the cause a quick interview with production shift management of particular department is needed.

At production control point P2 value OPSQ indicator falls below 5%. In most of European automotive companies at paint shop orders are reshuffle in order to build up particular color block. For orders no. 8,9,0,14 to production cycle flow indicators grows over critical value. On basis of Table 3 it can be identified that disturbances in production sequence are caused potentially by:

1.b non-standard supply lead times,  
2.b poor quality,  
3.b lack of needed components  

As mentioned before the non-standard production can be excluded. At paint shop all chemicals used are rather standard and repetitive so if a lack of paint or other chemicals appear more POINs should be delayed (XYLong) indicator over critical value). It can be identified that disturbances in production sequence between P1 and P2 (at
paint shop) are caused by poor quality. Paint shop is usually a bottleneck in number of automotive companies. The characteristics of paint process results in a big amount of failures that need to be reprocess e.g. not appropriate paint coat, workers hairs or fibers from clothing stick to lack. At final assembly none disturbances have been identified. At production control point FC OPSQ value falls again below critical value. It is a place in production system when technological process is finished and car is ready to be tested. The only disturbance among lb-3b that can cause deviation in production in initial production sequence at final control is poor quality due to the fact that there are no components used. Cars (POIN 11 &15) need to be reworked, time consuming re-processing is illustrated by increased in XYLong at A2-FC part of production system.

5. CONCLUSIONS

The automotive production systems are very complex and very often it is difficult to under pressure of time to analyzed production database in order to identified disturbance. The paper presents quick scan approach that can be applied in European automotive industry. The proposed approach is designed as a help for production controllers in order to easily exclude some of potential types of disturbances by observation of few simply indicators. The application of method required the knowledge about the production system organizational conditions and main design characteristics. The further research enhances the implementation of proposed indicators into production information management system for continuous (on-line) monitoring of production plans execution. The presented research was strongly case-based oriented however due the fact that manufacturing systems of the European automotive manufacturers are similar the proposed solution might be applied as well for other companies in the sector.

Application of Reverse Logistics for Remanufacturing in Electro-Mechanical Industrial Sector

Sahar El Barky, William Ion, Aziz El Sayed (*)
Design, Manufacturing Engineering Management Department
University of Strathclyde
Glasgow, G1 1XJ, UK

ABSTRACT

Recovery strategy is one the practical methods which supports sustainable objectives. Environmental policies and legislation, economic benefits and increasing customer awareness of green products are the main drivers for the extension of recovery strategies in the industrial and service sectors. Remanufacturing is preferable to recycling due to the saving of the initial value added to the raw material in producing the final product. Remanufacturing is "The process of returning a used product to at least OEM original performance specification from the customers’ perspective and giving the resultant product a warranty that is at least equal to that of a newly manufactured equivalent". The steady supply of core product is critical for remanufacturing as without it, it clearly cannot proceed. The complexity of the remanufacturing process lies in the uncertainty in the timing, quality and quantity of used products. The movement of used products from the consumer to the producer in distribution channel is defined as reverse logistics. Through reverse logistics activities, the assessment of used products is important to the overall profitability of the remanufacturing process. The decision for accepting or rejecting the used product is based on suitability for remanufacturing and is made by the dealers or OEM. Due to the lack of assessment criteria and guidelines for the assessment process, the used product assessment may be erroneous and it depends almost entirely on the experience. This paper will describe the previous work in the reverse logistics for remanufacturing. Also, it will present a proposed model showing the interaction between remanufacturing processes and reverse logistics activities. Finally, it will propose the research objectives and methodology which focus on the assessment criteria of core products and the relation between the nominal quality and acquisition price of used product. It present the initial findings of conducting industrial case study in Egypt.

1.INTRODUCTION

“Remanufacturing is the process of returning a used product to at least OEM original performance specification from the customers’ perspective and giving the resultant product a warranty that is at least equal to that of a newly manufactured equivalent” [41]. Many authors pointed out that the main drivers to the growth of remanufacturing as organized industrial sectors in many countries are as follows [7, 41, 35, and 3]:
− Legislation or take-back obligation issued by the European Union to push product recovery such as: WEEE, RoSH directive and EuP directive on the eco-design of energy-using products.
− Economic benefits by saving material and, energy cost.
− Market demand for cheaper products
− Increasing customers awareness for ‘green’ products and companies

Since the end of the 1970s, many authors have highlighted the ecological, social, and economic benefits of remanufacturing. Because of benefits, remanufacturing is considered a successful strategy for developing sustainable manufacturing. Past work gave examples of the best practice in remanufacturing strategy in the electro-mechanical sector [27, 29].

The process of remanufacturing became clarified when Ijomah developed a generic model of the remanufacturing business model, illustrating the activities of remanufacturing and their inter-relationships [40]. The activities are receiving core (used product), clean and strip the core, investigate the core, component
remanufacturing and inspection and testing. The author declared that the supply of the core (the used product), is critical for starting remanufacturing because it cannot proceed without used product to remanufacture. Also, if the supply of used products is inadequate then remanufacture, when it is able to proceed, must rely on new components rather than components cannibalized from used products [40]. Consequently, designing effective and efficient reverse supply chain system is a prerequisite for remanufacturing and a key driver for providing the economic benefits necessary to initiate and sustain customer relationship and customer loyalty [37, 4].

2. Reverse supply chain/Reverse Logistics activities

Pohlen and Farris define Reverse Logistics, guided by marketing principles, as being: “The movement of goods from a consumer towards a producer in a channel of distribution” [19]. Rogers and Tibben-Lembke describe Reverse Logistics as “the process of planning, implementing, and controlling the efficient, cost effective flow of raw materials, in – process inventory, finished goods and related information from the point of consumption to the point of origin for the purpose of recapturing value or proper disposal” [34]. Other authors state that reverse supply chain processes can be organized sequentially in five steps: product acquisition, transportation and warehousing, inspection, recovery process, and distribution and sales [23, 4, 37, and 26].

Starting with the acquisition process, Guide and Wassenhove state that product acquisition management is a key input to assessing the potential economic attractiveness of remanufacture activities [14]. This process is responsible for core acquisition in order to ensure adequate supply of cores for remanufacturing. As well, the authors rejected the idea that the firm should accept all used product returns from waste stream and show that a system for acceptance control exists. There are three major sources of used products [4]: Forward supply chain such as returns from defective or damage products and product recalls, Market driven systems, and Waste stream.

In a market driven systems, the used products returns to OEMs, retailers, dealers and third parties from the customer using different financial incentives policies such as, deposit based, credit based, buy back. Through those incentives companies are willing to obtain higher quality products for a fee. Consequently, there is less variability in the quality of used product. Large numbers of firms acquires cores directly from the customer (81.8%) by applying a trade-in or credit strategy when a remanufactured product is purchased. Those firms noticed that customer were motivated to return the products by themselves [4, 14]. Ostlin has defined other incentives such as ownership-based, service contract, direct order and voluntary based [12].

The cores are assessed in order to ensure their suitability for remanufacturing and if credit incentive is applied the price regarding to the quality of the cores are determined. Most likely, this assessment is done by the retailer or dealers. Ijomah clarified that the examination of quality of the components that make up the core are very important. Because inadequate components assessment have significant negative financial repercussions such as the discarding of good components and the use of inappropriate labour. Although, core assessment is critically important, there are a few guidelines to assist accurate component evaluation leading to excessive dependence on the experience of labours [40, 41]. The author identified the problems resulting from the shortage of documented assessment criteria and procedure as follows: inconsistency of parts inspections, excessive waste, inadequate training and poor performance monitoring. Moreover, Guide and Wassenhove claimed that the relation between nominal quality levels and acquisition price of used product should be identified in order to facilitate the effective management of core acquisition [14].
The model in figure 2 shows the interaction between reverse logistics activities and the remanufacturing process starting and demonstrates the decision points in the whole process. The model has been developed by the author from the literature and is based on two existing models: the framework for reverse logistics and a generic remanufacturing process flowchart [34, 40].

The first model of Mitra which similar to the frameworks presented by Fleischmann and Bloemhof-Ruwaard [23, 13] was selected because the model was developed upon survey on considerable number of case studies in different industries which address the design of logistics networks in a product recovery context. The model identified the recurrent reverse logistics in product recovery networks. The second model is selected because it obviously demonstrates the remanufacturing processes in details. The model validated by over 20 remanufacturing companies. Therefore, the model became a generic model for remanufacturing. The proposed model will be developed through conducting in-depth investigation of the case study.

3. PREVIOUS STUDIES OF THE REVERSE LOGISTICS

The research done in reverse logistics (RL) is mostly in practitioner-related rather than academic journals. Fleischmann notes that the literature is divided into three research areas: distribution planning, inventory control, and production planning [24]. In contrast, Dowlatshahi classified the literature according to five categories: global concepts; quantitative models; distribution, warehousing and transportation; company profiles; and applications [34]. The author stated that “the majority of the articles show lack of depth, do not describe the basic structure of Reverse Logistics, and do not define the basic concepts and terms”. Then, attention to the literature and the strategic and operational factors in Reverse Logistics systems is listed by the author. Most of scholars addressed the reverse logistics for recycling and a few for remanufacturing [15]. The following literature investigates only previous studies of Reverse Logistics network for remanufacturing.

3.1. QUANTITATIVE ANALYSIS

Simulation is a common method that is applied in quantitative methods. The method of system simulation rapidly and conveniently assesses various comprehensive reverse logistics networks under different scenarios. Consequently, an optimized network structure may be decided. Quite a few mathematical models are proposed in various literatures to optimize reverse logistics system. Fleischmann reviewed the previous quantitative models for reverse logistics network [24]. Jayaraman [38] established a mixed integer programming model that simultaneously solves for the location of remanufacturing/distribution facilities, the trans-shipment, production, and stocking of optimal quantities of remanufactured products and cores. The authors discussed the managerial uses of the model for logistics decision-making.

Krumwiede and Sheu developed a reverse logistics decision-making model to guide the process of examining the feasibility of implementing reverse logistics in third-party providers such as transportation companies [5]. Lourenço and Pablo developed a medium term production planning model dealing with the two new concepts: Partnerships and Reverse Logistics [10]. Jayaraman proposed a mathematical programming model for the management of product return flows, induced by various forms of reuse of products and material [37]. Pochampally proposed a newly developed method called physical programming to identify potential facilities in a set of candidate recovery facilities operating in a region where a reverse supply chain is to be established [17].

Savaskan addressed the problem of choosing the appropriate reverse channel structure for the collection of used products from customers for remanufacturing [31]. The authors modeled the three options for collecting the used product namely from the manufacturer, the retailer and third party. The authors found that the most effective method of product collection activity for the manufacturer is the retailer. Beamon cited by Mutha and Pokharel have developed an integer programming model for a four level reverse supply chain by assuming infinite storage capacities and same holding costs for recovered and new products [2,1]. In the same year, Kusumastuti proposed a multi objective and multi-period mixed integer linear programming model for network design for modularized products. The authors used the model to determine the number of existing forward flow facilities and the number of dedicated facilities to be set up for handling return flow [28]. Kim have proposed a general framework for remanufacturing environment and a mathematical model to maximize the total cost savings by optimally deciding the quantity of parts to be processed at each remanufacturing facilities, the number of purchased parts from subcontractor [16].
Figure 2: Proposed model demonstrates the interaction between reverse logistics activities and remanufacturing based on Mirta [34] and Ijomah [40].
Kara has presented a simulation model of a reverse logistics networks for collecting EOL electrical appliances in the Sydney Metropolitan Area [18]. The simulation results showed that the model calculates the collection cost in a predictable manner. Moreover, it provides a tool to understand how the system behaves by carrying out what-if assessments. Finally, the authors suggested that the low cost can be achieved when local councils act as collectors. In the same year, Listes proposed a generic stochastic model for the design of networks comprising both supply and return channels, organized in a closed loop system [26].

Lu and Bostal proposed mixed integer model to solve a two-level location problem with three types of facility to be located in a specific reverse logistics system, namely a ReManufacturing Network (RMN) [42]. The model considers simultaneously the forward and reverse flows and their common interactions. Wojanowski presented a continuous modeling framework for designing a drop-off facility network and determining the sales price that maximize the firm’s profit under a given deposit–refund [30]. Lee and Dong have developed a deterministic programming model for systematically managing forward and reverse logistics flows [30]. Srivastava provided an integrated holistic conceptual framework that combines descriptive modeling with optimization techniques at the methodological level [36].

**QUALITATIVE ANALYSIS AND CASE STUDIES**

De Brito reported that there are more 60 case studies for reverse logistics for different recovery processes. Approximately 60% of the cases are in the manufacturing category; about 20% are within wholesale and retail trade and about 10% in construction. However, to a certain extent a few authors investigated reverse logistics network for reverse logistics for remanufacturing field using case studies. It is observed that almost half of them deal with metal products, machinery and equipment and the majority of the cases are on products with high value [21].

Thierry declared that Recovery options that need take back of product may be classified as two kinds: direct recovery and process recovery. Recovery options can be summarized from various publications as: reuse, repair, remanufacturing, recycling and disposal [25].

Dijkhuizen discussed the remanufacturing network of IBM. The author dealt with the problem of where to re-process the products: in each country, or centrally at one place in Europe [9]. Meijer discussed the remanufacturing of used scanners, printers, copiers, faxes at Canon [8]. Krikke analyzed reverse logistics for remanufacturing of photocopiers [11]. The authors proposed a multi integer linear programming model to determine optimal location for preparation and reassembly operations. Guide clarified that some suppliers for toner cartridges, including UNISYS, deliver their cartridge in a box that can be returned for free to them or via another third party logistics service provider like Hewlett Packard or Xerox [15]. Also, Guide and Wassenhove discussed acquisition price incentive through a U.S. cellular phone remanufacturer that is also very active in setting prices to buy used mobile phones in the Business to Business environment [14].

Toktay et al described special example of service returns on Kodak’s single use camera. The authors proposed a closed queuing network model to determine a cost-efficient order policy for the external supplies. Major difficulties are largely unknown and difficult to observe from return probabilities and market distribution [20]. They assessed the importance of information on the returns for the control of the network. Fleischmann et al answered the following question: What activities are involved in reverse logistics? The authors identified main differences between the recovery networks: links with other networks; open vs. closed loop structure; and degree of branch cooperation. Moreover, they pointed out the classification scheme for different types of recovery networks: bulk recycling network; assembly product remanufacturing network; and re-usable item network. The authors proposed generic facility location model which is used to analyze the impact of product return flows on logistics networks [22].

De Brito and Dekker answered the following question: Why do companies pursue reverse logistics? The authors categorized the driving forces under three headings: Economics, legislation and extended responsibility. Additionally, reverse logistics is the main source for supplying used products for the companies in order to establish product recovery actions such as remanufacturing [21]. Ravi et al presented an analytic network process (ANP) based decision model to analyze the options in reverse logistics (RL) for end-of-life computers and link them to the determinants, dimensions and enablers of reverse logistics (RL) [29]. The model links the financial and non-financial, tangible and intangible, internal and external factors, thus providing a holistic framework for the selection of an alternative for the reverse logistics operations for end of life (EOL) computers.
4. SUMMARY OF THE LITERATURE

The literature shows that the assessment process of used product during reverse logistics is significant research problem as the incident leading to model development could be unique. Therefore, the research emphasizes on developing an integrated model for reverse logistics to remanufacturing in electro-mechanical sector. The model identifies the optimal criteria for acceptance the suitable used product in hierarchical form.

5. RESEARCH METHODOLOGY

To find appropriate companies for being case studies, a background study carried out through collecting data via semi-structured interviews with many companies in electro mechanical sector in Egypt. These interviews were conducted via telephone and emails in order to find out which of those companies are apply reverse logistics system for remanufacturing. The case study is an authorized dealer for Caterpillar as an OEM. Caterpillar is one of the leaders in applying reverse logistics for remanufacturing strategy all over the world. The choice of Case Study Company was made based on the following: Annual remanufacturing volumes; Relation to OEMs; Product complexity and accessibility. The research follows an inductive pattern because the study is based on a transition from specific observation and practical collected data from case study to broader generalizations and ultimately theories.

In the initial investigation, the reverse logistics current system is investigated supported by observation, documentation and interviews with key company personnel. The next section shows the application of credit strategy and the criteria which used by dealers during the assessment process. The work will compare the initial findings of the current system in the case with the proposed model from the literature in order to identify the gaps between the literature and practical application. The gap analysis will be the basis for developing the proposed model. The developed mode will be validated through identifying different scenarios, and running considerable number of experiments using focus group. The research paradigm is integrated between qualitative and quantitative data in order to establish the model because it is useful to explore a host of factors that may be affecting reverse logistics activities which not addressed obviously in the literature.

6. APPLICATION OF CORE CHARGE/CREDIT PHILOSOPHY

According to Östlin, the customers can receive credits for the type of cores they supply to the company. As a result, this means that the customer can return cores without purchasing a remanufactured product. The amount of credit the customers gain from the supplied cores is dependent on the state of the core, and the credit they have acquired gives them a discount when ordering a new remanufactured product [12].

![Diagram of core and credit flow](image)

Figure 3: Illustration of the core and credit flow between customer, dealers and remanufacturer

Credits are given according to two factors: first, the quality level of the core, and if any of the specific components in the core are missing; second, the amount of credit given, is also variable between different types of products, with cores in higher demand given a higher credit, and lower credit given for cores with lower demand. In this way, the remanufacturer gets a variety of cores and can practice some level of control through the credit system, while the customer can return cores for credit. This type of system enables the remanufacturer to control the balance between the supply and demand. The credit system can also work as a method for assessing the incoming quality level of the cores according to the number of credits given for returned cores. Comparable to, The initial findings of the interviews shows that the case study company applies “core charge/credit” philosophy in order to the following reasons:

– Ensure the timely return of cores fundamental to the successful operation of an exchange program.
– Prevent unplanned discounts which would result if users purchased Remanufactured Products without intending to return an acceptable one.

– Encourage the customer to return the core and buy the remanufactured product.

Cores qualified for exchange credit are those received by the dealers from the sale of corresponding remanufactured products to users. Therefore, the quantity of exchange credits for which a dealer is eligible will not exceed the quantity of corresponding remanufactured products purchased from the company. The types of core credit which are available for dealers are classified to the following:

– Exchange credit: when the core received by the dealer resulted from the sales of a corresponding remanufactured product purchased from the company.

– Direct purchase credit: for a core which resulted from other than a sale of a remanufactured product.

– Warranty credit: for a core resulting from the use of the company remanufactured product in warranty repair.

– Dealer surplus returns: Remanufactured products are returnable to the company on the same basis as new products.

7. CORE ACCEPTANCE CRITERIA GUIDELINES IN ELECTRO-MECHANICAL SECTOR

The core acceptance criteria used by dealer during inspection process to determine if a core is eligible for exchange credit. Table 1 shows the acceptance criteria for camshafts which concluded from the interviews and the documentation provided. Also, the price is evaluated according to level of deposit refund which can be full core deposit refund or damage core refund. For instance, a few product groups, such as camshafts have two levels of possible core deposit refunds. In some circumstances, the core credit will be reduced if major parts are missing or damaged in the core. After inspection, the proper core handling, packaging and labeling are done and the cores are stored until transporting to remanufacturing center.

</table>
8. CONCLUSION

The above discussion shows that topics which need to be covered in reverse logistics not only the networking structure and inventory analysis. The collection of used products, their pricing and their suitability to recovery strategy through an establish system are key area for further research.

This paper has illustrated the previous work in the reverse logistics for remanufacturing. The proposed model demonstrated the interaction between reverse logistics activities and remanufacturing processes. Also, the paper explained the application of credit strategy in reality as incentive strategy to return back used product in electro-mechanical sector. Finally, the core acceptance criteria are presented to help dealers and OEMs during core assessment process through conducing case study. In future, an integrated model of reverse logistics for remanufacturing will be developed. The model will identify optimal criteria for acceptance the suitable used product in hierarchical form based on the practical data of different products based on conducting the case study and literature.

\textbf{ABSTRACT}

This paper considers a stochastic job-shop scheduling problem. Many real world scheduling problems address probabilistic behavior in process times, due dates or other parameters. A job-shop scheduling problem was considered with stochastic process times and possible machine breakdowns. Distribution functions of process times are supposed to be known. Also, life times of machines are assumed to be exponentially distributed. In stochastic scheduling problems, unlike the deterministic variants, the solution cannot be fully determined a priori. In other words, every time a machine becomes available, a job has to be chosen to be passed on it from all the jobs that are waiting in line. The objective usually would be minimization of some measure consisting total tardiness and earliness. A solution to such a problem consists of two parts:

1. A strategy (rule) to choose one job from the jobs that are waiting in line
2. Near optimal values of start times of jobs

A heuristic rule based was devised on the famous central limit theorem to choose the job that should be passed on the freed machine. Also, an extensive simulation was used and a special push-forward technique to optimize start times and evaluate our solution method.

\section{INTRODUCTION}

Job-shop scheduling is a well-known NP-hard problem which has spurred an extensive and rapidly growing body of literature [1]. However, when uncertain parameters are included in the problem, very few works are addressed [2-7]. Uncertainty can be incorporated in Job-shop scheduling as stochastic or fuzzy parameters and on-line facets. Also the problem can be static, where a schedule is generated once, and dynamic, where the solution may or should be modified in discrete time horizons.

When parameters of Job-shop scheduling are random variables of known probability distributions, the problem belongs to the wide category of stochastic combinatorial optimization problems. For instance due dates, process times, cost parameters and technological precedence of operations can be random variables. In this case, the objective function may involve quantities such as expected value and variance of tardiness and inventory cost, probability of violation of due date constraints and so on. A solution method for stochastic job-shop scheduling is discussed in the context of stochastic optimization. Despite of being hard to solve, stochastic job-shop scheduling problem is very appealing to be challenged because most real-world situations include some levels of randomness.

As mentioned before, in stochastic combinatorial optimization problems uncertain information is described by means of random variables of known probability distributions. A more precise definition of stochastic combinatorial optimization problems is given in [8]. Static stochastic combinatorial optimization problems are characterized by the fact that decisions, or equivalently, the identification of a possibly optimal solution is done before the actual realization of random variables. This framework is applicable when a given solution may be applied with no modifications (or very small ones) once the actual realizations of random variables are known. This type of problems is also addressed in the literature as a-priori optimization. Dynamic stochastic combinatorial optimization problems arise when it is not possible or convenient to design a solution that is usable as it is for any realization of

\textsuperscript{*}Corresponding author: Tel. : (+98) 2166413034; fax: (+98) 2166413025; E-mail: fatemi@aut.ac.ir
the random parameters. In this case, decisions must be taken also after the random events have happened. This could also be done in stages, because it is often the case that the uncertain information is not revealed all at once, but in some stages. Roughly expressed, a dynamic stochastic combinatorial optimization problem is the one where decisions are taken at discrete times \( t = 1, 2, \ldots, T \), the horizon \( T \) being finite or infinite. In dynamic stochastic combinatorial optimization problems the concept of solution used in the static variants, which is similar to the concept of solution in their deterministic variants, is no longer valid. Here a solution is a policy or strategy that is adopted at each time horizon \( t \). In other words, a policy is a set of rules that says what action will be taken for each possible random future event.

In job-shop scheduling, probably the first thing that comes in to mind regarding stochastic facets, is the situation where process times are random variables. In such a problem, it is not possible to decide the precedence for processing jobs on each machine beforehand (unlike the deterministic variants). In other words, at the time that a machine is freed, a decision should be made to specify the job that should be passed on it. This calls for devising a rule or strategy (like the famous “first come first service” rule) to choose a job. While there are some works that have considered stochasticity in job-shop scheduling [2-7], the only paper was found that addresses this rule-based situation is [2]. In this paper, choosing a job from the line is carried out by using a cost-based decision-making rule. A pair wise comparison is raised among the competing jobs (jobs that are waiting in line for the freed machine) and the winner is passed on the machine. The decision-making rule, which is the basis of the competition, is carried out by obtaining the expected value of total costs of competing jobs. This paper uses the central limit theorem to estimate the costs. However, in [2] machine breakdowns are not considered. The same approach was used as [2] but it also is assumed that machines may breakdown during processing jobs.

2. DESCRIPTION OF THE PROBLEM

The problem considers a manufacturing cell with a set of \( N \) jobs and a set of \( M \) machines. Each job (order) consists of a sequence of \( M \) operations, each of which needs to be processed on a unique given machine. Preemption is not allowed but if a machine breaks down while it is processing a job, it should continue that job right after being repaired. Life times of machines are exponentially distributed. Now it is defined the following notations \((1 \leq i \leq M, 1 \leq j \leq N)\):

- \( p_{ij} \): random variable representing the process time of the \( i \)'th operation of job \( j \)
- \( \bar{p}_{ij} \): expected value of \( p_{ij} \)
- \( \sigma_{ij} \): standard deviation of \( p_{ij} \)
- \( y_i \): exponential random variable representing the life time of machine \( i \)
- \( \lambda_i \): the parameter of the exponential distribution of \( y_i \), i.e. \( f_i(y) = \lambda_i e^{-\lambda_i y} \)
- \( f_i \): the fixed value of repair time of machine \( i \)
- \( d_j \): due date of job \( j \)
- \( c_j^1 \): the penalty that should be paid for each time unit that job \( j \) is finished before \( d_j \)
- \( c_j^2 \): the penalty or tardy cost that should be paid for each time unit that job \( j \) is finished after \( d_j \)
- \( c_j^3 \): the penalty or tardy cost that should be paid for not delivering job \( j \) on time (to be paid once to the customer)
- \( St_j \): the start time of job \( j \), i.e. job \( j \) is not allowed undergoing any process sooner than \( St_j \) (decision variable)

Our objective is to obtain two issues in order to minimize the total inventory and tardy costs: a heuristic strategy or rule that specifies which job should be passed on a machine once it is freed (however if at most one job is ready to be processed on the freed machine there is nothing to decide), and near optimal values for \( St_j \)'s.

The problem was defined here is a dynamic or, as it is called in the literature, a reactive job-shop scheduling. Such a job-shop problem may be shown as “\( \sum_i w_i \sum_j T_j^i + w_j E_j^j \)” [9]. In problems that tardy and inventory costs exist, the issue of determining \( St_j \)'s arises and this is the situation we are dealing with here.
3. HEURISTIC STRATEGY

The heuristic strategy we are about to develop is similar to the decision-making rule with cost parameters method devised in [2]. However, major differences could be seen due to our approach and the fact that machines may break down. Assume that at time horizon t a set of jobs, namely \( C^j_{m} \), are competing for machine m. Now let us introduce some notations:

- \( m_{ij} \): the machine that processes the k'th operation of job j, \( 1 \leq k \leq M, 1 \leq j \leq N \)
- \( p'_{ij} \): the operational time that job j will be in the shop floor from the time its \( (x-1) \)'th operation is finished, where \( j \in C^j_{m} \) (\( m = m_{ij} \))
- \( \bar{p}'_{ij} \): expected value of \( p'_{ij} \)
- \( \sigma'_{ij} \): standard deviation of \( p'_{ij} \)
- \( C^j_{i} \): total cost of job j if at time horizon t job j is passed on machine m and on condition that job j never waits in line in future where \( j \in C^j_{m} \)
- \( C^j_{kij} \): total cost of job j if at time horizon t job \( j_k \) is passed on machine m and immediately after this event job \( j_1 \) is passed on machine m and never waits in line for any other machine in the future, \( j_1, j_2 \in C^j_{m} \)

Expected value of \( C^j_{i} \) and \( C^j_{kij} \) are calculated in Section 3.1. In the definition of \( C^j_{i} \) and \( C^j_{kij} \), it has been assumed that \( j \) and \( j_k \), respectively, will not wait in any line in future. This assumption, despite of being very critical for the following analysis and also the analysis that it will be carried out in section 3.1, is not realistic. However, as we are devising a heuristic rule (not an exact one), the result is applicable for setting up a comparison framework between jobs. Besides, one should pay attention that the assumption, although being unrealistic, is supposed to hold for all jobs that are in the same position and this creates a fairer situation. Now let us assume that jobs \( j_1, j_2, \ldots, j_n \) are competing for machine i at time horizon t. If \( E[C^1_i] + E[C^1_{k_i} < E[C^1_{k_i}] + E[C^1_{k_h}] \), then it is inferable that in a comparison between job \( j_1 \) and job \( j_2 \), it is probably less costly to select \( j_1 \). Further, the winner can be set up against \( j_3 \) and this pairwise comparison can be continued to the last job. The final winner is passed on the machine.

3.1. ON COMPUTING \( E[C^1_i] \) AND \( E[C^1_{k_h}] \)

To compute these cost parameters, like [2], we make use of the well known central limit theorem. It can be understood if now machine breakdown could happen, then \( \bar{p}'_{ij} = \sum_{i=x}^{M} \bar{p}'_{ij} \) and \( \sigma'_{ij} = \sqrt{\sum_{i=x}^{M} \sigma^2_{ij}} \). However, by conditioning on the number of breakdowns during the process of job j, one can prove the following two equations:

\[
\bar{p}'_{ij} = \sum_{i=x}^{M} \left[ \frac{1}{\lambda_{m_{ij}}} + f_{m_{ij}} \right] \left( 1 - p'^*_{ij} \right) + \bar{p}'_{ij} \tag{1}
\]

\[
\sigma'_{ij} = \sqrt{\sum_{i=x}^{M} \left[ 1 - p'^*_{ij} \right] \lambda^2_{m_{ij}} + \left( \frac{2}{\lambda_i} + f^2_{m_{ij}} + \frac{2f_{m_{ij}}}{\lambda_{m_{ij}}} \right) \left( 1 - p'^*_{ij} \right) \left( \frac{1}{\lambda_{m_{ij}}} + f_{m_{ij}} \right)^2 \left( 1 - p'^*_{ij} \right)^2 + 2 \left( \frac{1}{\lambda_{m_{ij}}} + f_{m_{ij}} \right)^2 \left( 1 - p'^*_{ij} \right)^3 + \sigma^2_{p^*} \left( 2 - p'^*_{ij} \right) + \sigma^2_{\sigma'^*} \right] \tag{2}
\]
where \( p_{ij}^* = \Pr[y_{m_i} > p_{ij}] \).

Now, according to the central limit theorem, one can say that if \( M - x + 1 \) is large enough then \( p'_{xj} \sim N(\tilde{p}_{xj}, \sigma'_{xj}) \) where \( N(\tilde{p}_{xj}, \sigma'_{xj}) \) is the normal density function with \( \tilde{p}_{xj} \) and \( \sigma'_{xj} \) as mean and standard deviation. Because \( p'_{xj} \geq 0 \), it is more appropriate to write \( p'_{xj} \sim N(\tilde{p}_{xj}, \sigma'_{xj}) (z \geq 0) = \frac{N(\tilde{p}_{xj}, \sigma'_{xj}) (z)}{1 - \Phi \left( \frac{-\tilde{p}_{xj}}{\sigma'_{xj}} \right)} \) where \( \Phi(z) \) is the cumulative distribution function of standard normal. For simplicity we use \( N(z) \) instead of \( N(\tilde{p}_{xj}, \sigma'_{xj}) \).

Now we have enough tools to compute \( E[C_i^x] \):

\[
C_i^x = \begin{cases} 
(d_j - t - p'_{xj})c_j^1 & \text{if } d_j - t - p'_{xj} \geq 0 \\
(p'_{xj} + t - d_j)c_j^3 + c_j^3 & \text{if } d_j - t - p'_{xj} < 0 
\end{cases} \implies 
\]

\[
E[C_i^x] = E[C_i^x \mid p'_{xj} \leq d_j - t] \Pr[p'_{xj} \leq d_j - t] + E[C_i^x \mid p'_{xj} > d_j - t] \Pr[p'_{xj} > d_j - t] = 
\]

\[
E[C_i^x \mid p'_{xj} \leq d_j - t] \int_{d_j - t}^{d_j - t - 1} N(z)dz + E[C_i^x \mid p'_{xj} > d_j - t] \int_{d_j - t}^{d_j - t - 1} N(z)dz \implies 
\]

After some algebraic operations and integrations, we can write:

\[
E[C_i^x] = c_i^1 \cdot d_j - t - \left( \Phi \left( \frac{d_j - t - \bar{p}_{xj}'}{\sigma'_{xj}} \right) - \Phi \left( \frac{-\bar{p}_{xj}'}{\sigma'_{xj}} \right) \right) - \left( \Phi \left( \frac{d_j - t - \bar{p}_{xj}'}{\sigma'_{xj}} \right) - \Phi \left( \frac{-\bar{p}_{xj}'}{\sigma'_{xj}} \right) \right) \times 
\]

\[
\Phi \left( \frac{d_j - t - \bar{p}_{xj}'}{\sigma'_{xj}} \right) - \Phi \left( \frac{-\bar{p}_{xj}'}{\sigma'_{xj}} \right) + 1 - \Phi \left( \frac{-\bar{p}_{xj}'}{\sigma'_{xj}} \right) 
\]

\[
\left( \left( \frac{\bar{p}_{xj}'}{\sigma'_{xj}} \right) 1 - \Phi \left( \frac{d_j - t - \bar{p}_{xj}'}{\sigma'_{xj}} \right) \right) + \frac{\sigma'_{xj}}{\sqrt{2\pi}} e^{-\frac{(d_j - t - \bar{p}_{xj})^2}{2\sigma^2_{xj}}} - c_j^3 \right) + t - d_j \right) c_j^3 + c_j^3 \right) \times \frac{1 - \Phi \left( \frac{d_j - t - \bar{p}_{xj}'}{\sigma'_{xj}} \right)}{1 - \Phi \left( \frac{-\bar{p}_{xj}'}{\sigma'_{xj}} \right)} \]

(3)

In order to calculate \( E[C_{i,kl}^x] \), the very same steps should be taken. It is easily understood that:
\[
C_{hj} = \begin{cases} 
(d_h - t - p'_{xh} - p_{oh})c_{ij}^h & \text{if } d_h - t - p'_{xh} - p_{oh} \geq 0 \\
(p'_{xh} + t + p_{oh} - d_h)c_{ij}^h + c_{ij}^3 & \text{if } d_h - t - p'_{xh} - p_{oh} < 0 
\end{cases}
\]

where \( m = m_{xh} \) and \( m = m_{oj2} \). Here we can write \( p'_{xh} + p_{oh} - N_{\bar{p}_{xh}, \bar{p}_{oj2}, \sigma_{xh}, \sigma_{oh}}(z) \) and then follow the same way we did for equation 3 to achieve an equation for \( C_{hj2} \). The desired result, which we do not bring here due to brevity, is obtained by replacing \( \bar{p}_{xh} \) by \( \bar{p}_{xh} + \bar{p}_{oj2} \) and \( \sigma_{xh} \) by \( \sigma_{xh} + \sigma_{oh} \), in equation 3.

4. Optimizing \( St_j \)'s

In order to optimize \( St_j \)'s we use a simple push forward algorithm. Roughly expressed, we consider jobs one by one (no special order), and we try to push the \( St_j \)'s forward as much as the total cost of the manufacturing cell decreases. The process of determining the costs for each \( St_j \) is done via simulation. In each step of the algorithm we increase the \( St_j \) for the considered job by a discretization step (since the \( St_j \)'s are continuous) and then use simulation to evaluate the total cost. Here, we define the following notations:

- \( DS_j \): discretization step for \( St_j \)
- \( I_{\text{max}} \): maximum number of simulation runs for each value of \( St_j \)
- \( St_j^s \): start time of job \( j \) in step \( s \) of the optimization algorithm
- \( TC_j^s \): mean total cost of shop floor in step \( s \) of the optimization algorithm while \( St_j \) is being optimized

Now, we propose the following algorithm:

1. let \( j=1 \) and \( s=1 \)
2. for \( J=1 \) to \( N \) let \( St_j^s = 0 \)
3. run the simulation model for \( I_{\text{max}} \) iterations and calculate \( TC_j^s \)
4. if \( j \leq N \) then
   \[ St_j^s \leftarrow St_j^s + DS_j, s \leftarrow s + 1 \]
   Else
   stop
5. run the simulation model for \( I_{\text{max}} \) iterations and calculate \( TC_j^s \)
6. if \( TC_j^s > TC_j^{s-1} \) then
   \[ St_j^s \leftarrow St_j^{s-1}, j \leftarrow j + 1, s \leftarrow 0, St_j^s \leftarrow -DS_j \] and go to 4
   Else
   go to 4

5. Computational Experiments

In order to verify the efficiency of the optimization algorithm and the heuristic strategy, experiments have been carried out. To have a suitable basis for comparison, the exact test problems used in [2] are also used here, that would be a job-shop manufacturing cell comprising 16 jobs and 8 machines. Since we are considering machine breakdowns, we do not expect the results to be as good as what is reported in [2]. However we bring the results of [2] to have a minimal basis of comparison. Process related parameters are given in Table 1. The data is presented in 3-tuple format \((x, y, z)\).

Table 2 contains cost parameters and due dates. Operations should be processed on machine \( x \) while three distributions of random process time have been considered:

1. Normal distribution with the mean \( y \) and the variance \( z \)
2. Uniform distribution on the interval \([y - 3\sqrt{z}, y + 3\sqrt{z}]\)

3. Exponential distribution with the mean \(y\)

Our method was implemented on an Intel® core™2 CPU T5600 that works at 1.83GHz with one gigabyte of RAM. The simulation model of the shop floor was run for 200 simulations for each test problem (\(I_{\text{max}} = 200\)).

</tbody>
</table>

In order to obtain meaningful values for \(D_{\text{ij}}\)'s, we first run the simulation model considering \(S_{\text{ij}} = 0\) for all jobs. Then we can calculate the value of standard deviation for the completion time for each job in the \(I_{\text{max}}\) iterations. This standard deviation divided by 10 and rounded up seems to be an appropriate value for \(D_{\text{ij}}\).

In the case of machine breakdowns, we let \(1 - \frac{1}{\lambda_i} = \sum_{j=1}^{N} \tilde{p}_{ij}\) and \(f_i = \left[ \frac{0.5}{\lambda_i} \right]\) to ensure that breakdowns are meaningfully probable to happen in the course of processing any job.

Tables 3, 4, 5 and 6 contain the results and comparisons of our method and the decision-making rule with cost parameters method presented in [2]. According to [2], all the average expenses reported for the decision-making rule with cost parameters method are also drawn from 200 simulation runs.

6. INTERPRETATION, CONCLUSION AND FUTURE WORKS

This paper considers a stochastic job shop scheduling problem with machine breakdowns. In stochastic job shop, every time a machine is freed, a rule is needed to choose one job from all the jobs which are in line to be passed on the machine. A heuristic rule was devised based on the central limit theorem to deal with this situation. The extensive simulation was used to test our rule. Based on the results of simulation (Tables 3 to 6) the following conclusions can be drawn:

1. Due to higher variance in total cost (which is also reported in [2]), many of \(t_j\)’s are computed to be zero in the case of exponential process times.
Table 6: Results of our method and decision-making rule with cost parameters [2]. Process times are Exponential

| Jobs | S_j^{'s of our method} | S_t^{'s of the decision-making rule with cost parameters [2] | |
|------|------------------------|----------------------------------------------------------|
| 1    | 0                      | 0                                                        |
| 2    | 121                    | 675                                                      |
| 3    | 0                      | 250                                                      |

| 5    | 0                      | 125                                                      |
| 6    | 382                    | 300                                                      |
| 7    | 38                     | 100                                                      |
| 8    | 0                      | 125                                                      |
| 9    | 412                    | 600                                                      |
| 10   | 0                      | 450                                                      |
| 11   | 0                      | 525                                                      |
| 12   | 0                      | 450                                                      |
| 13   | 461                    | 300                                                      |
| 14   | 0                      | 125                                                      |
| 15   | 0                      | 0                                                        |
| 16   | 118                    | 375                                                      |
| Total | 294575                | 213720                                                   |

2. Total cost of shop floor in our stochastic job-shop scheduling problems with machine breakdowns is more than what is reported in [2]. This is clearly because of our assumption about machine breakdowns. In other words, since machine may break during processing jobs, it takes longer for jobs to be finished. According to Table 2 costs of tardiness are much more than inventory costs (this is a realistic assumption). Therefore it can be concluded that higher costs in our problems are due to more tardy costs.

3. Start time of jobs in our method is, for most of jobs, less than what is reported in [2]. This happens because jobs should start sooner in order to compensate for higher tardy costs which are likely to happen due to machine breakdowns.

For future works on stochastic job shop scheduling, one can concentrate on more precise methods of decision making. One may argue that, at any time a competition is raised, the status of all the jobs in the shop floor can affect our decision. However no information was taken on the non-competing jobs in to consideration. This idea is being implemented on stochastic job shop scheduling by using the concept of markov decision process [10].

An innovative fuzzy time series model for forecasting

S.M.T. Fatemi Ghomi, M.R. Marjani*
Department of Industrial Engineering
Amirkabir University of Technology
Tehran, Iran

Abstract
Fuzzy time series models are major useful tools in forecasting based on vague or incomplete data. In recent years, there have been proposed different models to forecast more accurately. Fuzzification and establishment of fuzzy relations are two major steps of fuzzy time series, which have been touched in previous studies. It has been shown that fuzzification affects forecasting results in fuzzy time series. This study proposes a new method of fuzzy time series based on fuzzification improvement. The method has been applied on forecasting the enrollment of University of Alabama that has been considered in literature. Comparing the forecasted values with the results of prior methods demonstrate that the accuracy of proposed method in forecasting is superior to previous methods.

1. Introduction
Time series models are major useful tools in forecasting. However, if the historical data are very little or linguistic, the statistical methods could not be successful. Since linguistic values can easily be defined into fuzzy sets, fuzzy sets theory was naturally considered to deal with this situation and therefore the concept of fuzzy time series was proposed [1]. Due to its ability in problems with imprecise data, fuzzy time series models have attracted attention of many researchers in recent years. The major objective in this area of forecasting is to develop a method to providing more accuracy in the forecasted values [15].

Different methods have been proposed and studied to solve fuzzy time series problems. Each fuzzy time series essentially consists of three major steps: fuzzification, establishment of fuzzy relationships, and defuzzification. Some studies have focused on the fuzzification step [2 and 3]. Many studies also have focused on the establishment of fuzzy relationships [4-10].

This study focused on the fuzzification part of the fuzzy time series and its aim is to propose a new approach in interval definition. Here the assumption of equal and separate intervals is released and the intervals are defined by clustering the data. The structure of this paper is organized as follows: The last works in this area are reviewed in section 2. In section 3 the concepts of time series and method of interval definition are reviewed. The new method is proposed in section 4. In section 5, the performance of the model in forecasting Alabama University’s enrollments will be compared with other methods. Finally, summary and conclusions will be drawn in Section 6.

2. Literature review
Fuzzy time series was first introduced by Song and Chissom in 1993 [1,4 and 5]. They implemented the developed fuzzy time series models on the historical enrollment data of University of Alabama. Chen by using arithmetic operations presented a simplified method for time series forecasting [6]. Huarng proposed a heuristic model for time series forecasting using heuristic increasing and decreasing relations to improve the forecast of enrollments and also implemented it for TAIEX forecasting [8]. He also presented two approaches (distribution- and average-based) in determining lengths of intervals to improve forecasting with fuzzy time series [2]. Chen presented a new method based on high-order fuzzy time series [7]. He raised some points of ambiguity to the trend in forecast and suggested to use high-order fuzzy logical relationship groups to deal with ambiguity. On comparative study, the third-order

* Corresponding author: E-mail: fatemi@aut.ac.ir (S.M.T. Fatemi Ghomi), marjani@aut.ac.ir (M.R. Marjani)
model was found to have much more accuracy. Song extended the Chen’s model by proposing a method to select the best order for fuzzy time series model; he found that the third order was better than others [11]. Lee and Chou modified the Chen’s method of by redefining the Universe of discourse and subsequent partition of intervals [12]. Also Chen and Hsu proposed a new method in definition of the intervals by dividing the universe of discourse into intervals and then dividing these intervals into four, three, two and one according to the frequency of their occurrences and framed some rules for forecasting [13]. Yu presented a refined fuzzy time series model which can be used to adjust the lengths of the intervals determined during the early stages of forecasting, when the fuzzy relationships are formulated [3]. Yu, proposed weighted models to tackle both recurrence and weighting in fuzzy time series forecasting [10]. She argued that recurrent fuzzy relationships, which were simply ignored in previous studies, and different weights for various fuzzy relationships should be considered in forecasting. Own and Yu presented a heuristic higher-order model by introducing a heuristic function [14]. The trend of time series is used as the heuristic knowledge to specify the difference between times to an increase, a decrease or no change as a parameter. Tsaur et al., used the concept of entropy to measure the degree of fuzziness of a system and to determine a time T of which the data approaches steady state [15]. Huarng and Yu proposed the use of a type 2 fuzzy time series model to utilize more than one variable’s observations in forecasting [9]. In their Type 2 model, extra observations are used to enrich or to refine the fuzzy relationships obtained from Type 1 models and then to improve forecasting performance. Huarng and Yu, applied a back propagation neural network because of its nonlinear structures to forecast fuzzy time series [16]. They proposed two models: a basic model using a neural network approach to forecast all of the observations, and a hybrid model consisting of a neural network approach to forecast the known patterns as well as a simple method to forecast the unknown patterns. Singh, present a new method in fuzzy time series using a difference parameter as fuzzy relation for forecasting. It provides simple computational algorithms of complexity in linear order. It minimizes the time of generating relational equations by using complex min-max composition operations and the time consumed by the various defuzzification process [17]. Li and Cheng, proposes a novel deterministic forecasting model to control the uncertainty in forecasting. In addition, the maximum length of subsequence in a fuzzy time series resulting in a certain state is deterministically quantified [18].

3. REVIEW OF FUZZY TIME SERIES

The concepts of fuzzy time series found in [1–18] are summarized as follows:

Definition 1: Let \( Y(t) \) \((t = \ldots, 0, 1, 2, 3, \ldots)\), is a subset of real numbers, be the Universe of discourse on which fuzzy sets \( f_i(t) \), \((i = 1, 2, \ldots)\) are defined and \( F(t) \) is the collection of \( f_i(t) \), \((i = 1, 2, \ldots)\), then \( F(t) \) is defined as fuzzy time series on \( Y(t) \) \((t = \ldots, 0, 1, 2, 3, \ldots)\).

Definition 2: If \( F(t) \) is caused by \( F(t - 1) \) only, which is denoted by \( F(t - 1) \rightarrow F(t) \), then there exists a fuzzy relationship between \( F(t) \) and \( F(t - 1) \) and can be expressed as \( F(t) = F(t - 1) \times R(t, t - 1) \). Here, “\( X \)” is an operator. The relation \( R \) is called first-order model of \( F(t) \).

Definition 3: Suppose \( F(t) \) \((t = \ldots, 0, 1, 2, 3, \ldots)\), is a fuzzy time series. If for different times \( t_1 \) and \( t_2 \), \( R(t_1, t_1 - 1) = R(t_2, t_2 - 1) \), then \( F(t) \) is called a time invariant fuzzy time series.

Definition 4: If \( F(t) \) is caused by more fuzzy sets, \( F(t - n), F(t - n + 1), \ldots, F(t - 1) \), which is denoted by \( F(t - n), F(t - n + 1), \ldots, F(t - 1) \rightarrow F(t) \), then this relation is called \( n \)th order fuzzy time series model.

Definition 5: If \( F(t) \) is caused by \( F(t - 1), F(t - 2), \ldots, F(t - m) \), \((m > 0)\) simultaneously and the relations are time variant. The \( F(t) \) is said to be time variant fuzzy time series and the relation can be expressed as \( F(t) = F(t - 1) \times R^w(t, t - 1) \) Where, \( w > 1 \) is the number of years before \( t \) various complicated computational methods are available for the computations of the relation \( R^w(t, t - 1) \).

The procedure of fuzzy time series forecasting the enrollments proposed by Song and Chissom includes the following steps [4]:

1. Define the universe of discourse within which the historical data are and upon which the fuzzy sets will be defined,
2. Partition the universe of discourse into several even lengthy intervals,
3. Define the fuzzy sets on the universe,
4. Fuzzify the data, i.e. find out an equivalent fuzzy set to each data,
5. Establish the fuzzy relationships from the historical knowledge,
6- Calculate the Forecast outputs,
7- Defuzzify the forecasting results.

Song and Chissom, time-variant model is similar to their time-invariant model except in step except in Establishing the fuzzy relationships and forecasting, which they choose a model basis w and calculate extrapolation operator RW (t, t - 1) to forecast [5].

Chen proposed a new model, which used arithmetic operation [6]. His model did not need numerous calculations. Chen also proposed a method of forecasting enrollments based on high-order fuzzy time series of various orders: second, third, fourth and fifth, this was appeared in establishment of the relationships [7]. The main structure of all this models is similar. They all have fuzzification the data, establishment the rules for forecasting and defuzzification. Huarng, has showed that in fuzzification process, different lengths of intervals will lead to different forecasting results. However, shorter intervals lead to results that are more accurate [2]. He proposed that the effective lengths of intervals be used. The algorithm for determining the distribution length of intervals is as follows [2]:

1- Calculate all the absolute differences between of data and the average of them.
2- Determine the base for length of intervals according to the average.
3- Plot the cumulative distribution of the first differences.
4- The largest length that is smaller than at least half the first differences is choose as the length of intervals.

Moreover, the Algorithm for average-based length is [2]:

1- Calculate all the absolute differences between of data and the average of them.
2- Take one-half the average (in step 1) as the length.
3- Determine the base for length of intervals according to the length (in step 2).
4- Round the length according to the determined base as the length of intervals.

4. NEW METHOD IN DETERMINING THE LENGTH OF INTERVALS

As it is said before, the fuzzy time series consists of three major processes: fuzzification, the establishment of fuzzy relationships and defuzzification. This study focused on the first one, i.e. it presented a new method in determining of fuzzy sets; although the defuzzification process is also changed. In all last works, there exists a hidden assumption that the intervals must be equal and separate. However, in the fuzzification process each data is defined by more than one interval and by the degree that this data belongs to each interval. While it is true, it can be obviously realized that the aim of these two steps as a whole is to define a certain number of fuzzy sets and determine the membership function of data in each fuzzy set. To do this, the fuzzy clustering can be used simply. Clustering is the unsupervised classification of patterns (observations, data items, or feature vectors) into groups (clusters) [19]. If fuzzy clustering is used to partitioning the data, there will be fuzzy sets with overlaps.

In this study the fuzzy C-mean algorithm is used for clustering. To do this first the data are sorted in an increasing order and are partitioned in certain number of fuzzy sets. To find out the equivalent fuzzy set of each data, it can be done the same as Song and Chissom, i.e. assume that if the maximum membership of one data is under fuzzy set $A_k$, then that data can be treated as $A_k$ [4]. Afterward, data are returned to prior order with assigned fuzzy sets to each one. It was observed that three or more successive data that was assigned to one fuzzy set in the original sequence may lead to big errors; because they have a same meaning in forecasting. To avoid these errors, it was suggested to increase the number of clusters one by one up to there is not any clusters with three or more successive data.

The algorithm of proposed method is:
1- Define the universe of discourse within which the historical data are.
2- Fuzzification: Sort the historical data in ascending manner and cluster them into certain number of fuzzy sets. Then rearrange the data in their prior sequence. If three or more successive data was assigned to one fuzzy set, then increase the number of clusters by one, and repeat this stage.
3- Establish the fuzzy relations and forecasting.
4- Defuzzification: here the cluster centers can be used simply.
The results of this contribution in both first and high order time series are great. This method is used in forecasting the enrollment of the University of Alabama and the results are compared with the results of other methods. The Fuzzy sets of enrollments data are shown in Table 1. The enrollment data of the University of Alabama and the equivalent fuzzy sets to each year's enrollment are shown in Table 2. The average of interval length in this method is 1081.2.

The fuzzy relations can be obtained from table 2 as follows:

\[ A_1 \rightarrow A_2, A_2 \rightarrow A_3, A_3 \rightarrow A_4, A_4 \rightarrow A_5, A_5 \rightarrow A_6, A_6 \rightarrow A_7, A_7 \rightarrow A_8, A_8 \rightarrow A_9, A_9 \rightarrow A_{10}, A_{10} \rightarrow A_{11}, A_{11} \rightarrow A_{12} \]

From the above relations and centers of fuzzy sets, these values are found out for forecasting:

\[ A_1 \rightarrow 13722, \quad A_2 \rightarrow \frac{13722 + 14695}{2} = 14208.5, \quad A_3 \rightarrow 15448, \quad \ldots \]

The results are shown in Table 2. This fuzzified data can be used in Chen’s high order models [7]. As it was said before, Chen’s comparative study showed that Third-order model lead to best results [7]. The fuzzified data is applied in Chen’s Third-order model. These results are shown in Table 3.

5. PERFORMANCE COMPARISON

To measure the accuracy of forecasting the Mean Square Error (MSE) can be calculated as follows:

\[
\text{Mean Square Error (MSE)} = \frac{1}{n} \sum_{i=1}^{n} (Actual_i - Forecast_i)^2
\]

In this section, the forecasting performance of the proposed fuzzy time series models on the University of Alabama enrollments data from 1971 to 1992 is compared with the previous models, which all used these data. The MSEs of their results are summarized in Table 6. The comparison of the MSE of forecasting in different models showed that the proposed models has the best results. It must be noticed that the average length of intervals determined by proposed method is 1081.2, which is a little more than 1000.

</tbody>
</table>

Also the performance of the proposed models are compared with other models in forecasting of wheat production from 1982 to 2000 and the results are summarized in table 7. The comparative study of MSE, as shown in Table 6 and table 7 shows that the forecast by the proposed methods are of higher accuracy over the other methods.
6. DISCUSSION

This study focused on both fuzzification and defuzzification processes of fuzzy time series. In this study an innovative method is presented to determine fuzzy sets. In all last works, there exists an assumption that the intervals of defined fuzzy sets must be equal and separate. Albeit in the fuzzification process each data is defined by degree of membership to each fuzzy set. Here, unlike last studies in this field, the fuzzy clustering has been used simply. This method led to unequal fuzzy sets with overlaps. The centers of these sets, which are used in forecasting process, have much more accuracy than others from previous methods. The comparative results confirm this. The number of fuzzy sets has a significant role in precision of forecasting results. Proposed method of determining the number of clusters is another effective aspect of this study.

7. SUMMERY

This paper proposed a new approach in fuzzy time series based forecasting. The fuzzy c-mean algorithm is used for clustering ordered data in certain number of fuzzy sets to find out best partitioning of data. In forecasting problems with limit or incomplete data, this model can reach to assured results. The proposed method, which has been implemented in both first and third order fuzzy time series models, led to obtaining satisfactory results. The new model has been applied on forecasting the enrollments of University of Alabama and wheat production to have a comparative study with the existing methods and outperform them with the least mean square errors. Thus, it can be applied to improve the forecasting based on fuzzy time series.

A new approach in performance evaluation with Artificial Neural Networks

Abdolhamid Safaei Ghadikolaei*, Ali Zareshahi

Mazandaran, Babolsar, Iran

ABSTRACT

There has been a long tradition in business and economics to use frontier analysis to assess a production unit’s performance. The first attempt utilized the data envelopment analyses (DEA) which use a mathematical programming approach. Recently someone use artificial neural networks (ANNs) for performance evaluation and show that ANNs are a promising alternative to traditional approaches, to approximate production functions more accurately and measure efficiency and productivity under non-linear contexts, with minimum assumption. Although ANNs have many priority on other performance evaluation methods, but when a Decision Making Unit (DMU) have multi outputs ANNs only offer multi efficiency score for each output and thereupon the final ranking for a DMU is not met. Therefore this paper presents a new approach in measuring efficiency by use of artificial neural network. According to this method every DMU and every output efficiency assumed as an alternative and attribute respectively. Finally Analytic Hierarchy Process (AHP) is applied to transform multi ranking to a single one for each DMU. For more perception, efficiency of 66 branches of Saderat bank in Iran was evaluated and results compared with traditional DEA models and DEA-ANN. results show that, every three methods have same trends in ranking and proposal method has satisfactory correlations with other perspectives.

1. INTRODUCTION

Productivity and efficiency in converting resource (inputs) into good and service (outputs) have been key issues in private and public sectors. There have been countless articles of efficiency analysis in the literature of operation research and econometrics. Efficiency frontier analysis has been an important approach of evaluating firms’ performance in private and public sectors [1]. Five different approaches, namely, data envelopment analysis (DEA), free disposal hull (FDH), stochastic frontier approach (SFA), also called econometric frontier approach (EFA), thick frontier approach (TFA), and distribution free approach (DFA), have been reported in the literature as frontier analysis methods to evaluate a decision making unit (DMU) efficiency. These approaches primarily differ in how much restriction is imposed on the specification of the best practice frontier and the assumption on random error and inefficiency [2].

Two first approaches mentioned above are non-parametric and remains are parametric approaches. The parametric frontier method assumes a particular functional form for the efficiency boundary. A procedure that is called corrected OLS (COLS) is used to measure technical inefficiency. For this purpose First an average practice frontier is estimated using OLS. Then this frontier is corrected by shifting the intercept until all residuals except one become negative. Hereby primitive average frontier (OLS) transformed to an envelopment frontier (COLS). Versus, non-parametric methods do not assume a particular production function. In this approaches a piece-wise linear frontier is directly constructed from the observations themselves by applying mathematical programming techniques [3]. Every one of these two approaches has its strength and weakness. Hence, recently some of researchers attempt to find a method to corporate two approaches strength. In this way, Reference [4] for the first introduces Artificial Neural Networks (ANN) as a non-parametric method for performance evaluation. Their application is bank with multi output: 4 inputs, 3 outputs. In this study researchers compare ANNs and DEA. In a simulation, they conclude that DEA is superior to the ANNs for measurement purposes and ANNs are similar to DEA for ranking units. Reference [5] analyses the London underground efficiency with time series data for 1970-1994 where there are 2 inputs: fleet and workers and 1 output: kms. They explain how the ANNs result similar to Corrected Ordinary Least Squares (COLS) and DEA, but ANNs offer advantages at the decision making, the impact of constant vs. variable returns to scale or congestion areas.

* Corresponding author: Tel.: (098) 112-5243001; Fax: (098) 112-5242705; E-mail: ab.safaei@umz.ac.ir
Reference [6] use a neural network for a simulated non-linear production function and compare its performance with traditional alternatives like stochastic frontier and DEA in different observations number and noise scenarios. Their results show that ANNs obtains robust estimations with few variations respecting true efficiency over number of DMUs and injected noise. MLP is superior to traditional techniques when underlying technology is under moderate noise together with more DMUs.

In another study Reference [7] compares some of parametric and non-parametric models by use of ANNs. In this study sample was 72 Spanish municipalities. The considered output is the solid waste and the inputs included the containers, vehicles and worked hours. Stochastic and deterministic Cobb-Douglas were two parametric models and FDH, DEACrs and DEAVrs were three non-parametric models that used in this study. Finding show that although several difference in the quantitative measures are evident, but there are a common trends in results so that the most and the lowest efficient units were identified by all the approaches.

Reference [8] use ANNs for measuring efficiency and productivity growth for seven East Asian economies at manufacturing level, for the period 1963-1998, and relevant comparisons are carried out between DEA and ANN, and SFA and ANN in order to test the ability of ANNs to assess the performance of production units. the sample in this study include 28 manufacturing sectors with 1 output-value added and 2 input-fixed capital formation and employment measured in numbers. Growth index decomposition shows that East Asian economic growth in the future will mainly rely on innovation that is technological progress.

All studies mentioned above, have a similar weakness that is their inability in encountering multi outputs. As observable above, References [5,7,8] use a model with 1 output because ANN calculate one efficiency for each output, therefore in the case that there are multiple outputs, management has multi score as efficiency for each DMU.Obviously in this instance management can not have a comprehensive ranking of DMUs. Then this paper uses AHP to propose a solution to corporate the output efficiency score calculated for each DMU. Proposal method does not require value judgment and therefore is an innovative solution.

Reference [2] proposes another school in performance evaluation by ANNs. They presented a DEA-ANN study for performance assessment of branches of a large Canadian bank. The results are operable to the normal DEA results on the whole. They concluded that the DEA-ANN approach produces a more robust frontier and identifies more efficient units because better performance patterns are explored. Furthermore, for worse performers, it provides the guidance on how to improve their performance to different efficiency ratings. Ultimately, they concluded the neural network approach requires no assumptions about the production function (the major drawback of the parametric approach) and it is highly flexible.

2. ANALYTICAL METHODOLOGY

This study use DEA, ANNs and DEA-ANN as three frontier analysis methods in performance evaluation.

2.1. DATA ENVOLPMENT ANALYSIS

Data Envelopment Analysis (DEA) is a mathematical model that measure the relative efficiency of decision making units with multiple inputs and outputs but with no obvious production function to aggregate the data in its entirety. Relative efficiency is defined as the ratio of total weighted output to total weighted input [9].

Let us assume a set of $j = \{1, \ldots, n\}$ DMUs to be evaluated. Each DMU consumes varied amounts of $m$ different inputs to produce $s$ different outputs. Specially, DMU $j$ consumes amount $x_{ij}$ of inputs ($i=1\ldots m$) and produce amounts $y_{rj}$ of outputs ($r=1\ldots s$). The efficiency of unit $k$ under the assumption of constant and variable returns to scale is given by the solution to the optimization problem in (1) and (2), respectively (Table 1). The formulation of these models has been proposed by [10] and [11]: Where $v_i$ is weight factor for input $i$ estimated by two models, $u_r$ is weight factor for output $r$ estimated by two models, $\omega$ is a sign free variable that characterizes the variable returns to scale model, $\epsilon$ is a non-Archimedean small positive number. Efficiency of unit $k$ is obtained under CRS as $E_k^{CRS} = \frac{1}{\sum_{i=1}^{m} v_i^* x_{ik}}$ and under VRS as $E_k^{VRS} = \frac{1}{\sum_{i=1}^{m} v_i^* x_{ik} - \omega}$ (where the asterisks indicate optimal values).

2.2. ARTIFICIAL NEURAL NETWORKS

In this section we give a brief review of neural network mechanisms and its applications in efficiency measurement.

2.2.1. A BRIEF REVIEW OF ARTIFICIAL NEURAL NETWORKS

An ANN is an information processing paradigm that is inspired by the way biological nervous systems, such as the brain, process information. ANNs have been applied when there is no theoretical evidence about the functional forms [12]. The Multi Layer Perceptron (MLP) is perhaps the most popular and widely applied of the many existing ANN types. Reference [13] has shown that subject to mild regularity conditions these models can approximate any function and its derivatives to any degree of accuracy. The MLP basic properties can be summarized in the triplet: multi-layer, feed-forward and supervised neural network. Its processing elements, known as ‘neurons’, are organized in at least three layers: the input layer, the output layer and the hidden layer(s) in between. These neurons are all fully connected between adjacent layers. MLPs are feed-forward networks, i.e. all connections point in one direction, from the input towards the output layer. Finally, they are supervised networks since all patterns of both inputs and outputs must be provided. The development of a neural network model requires the specification of a ‘network topology’ and a ‘training strategy’. The MLP topology is defined by the number of input and output neurons, the number of hidden layers and the number of neurons in each hidden layer. The training strategy refers to the procedure and technique used in estimating the optimal network parameters (known as ‘weights’) [5]. Training involves repeatedly presenting the data to the network. Learning is achieved in the network by altering the values of weighted connections between neurons to bring the output of the network closer to the desired target value. The overall aim is to reduce the Mean Squared-Error (MSE) for the training data. The errors between output and target values are propagated back through the network to attribute them to the weights in the network, these are then altered using the steepest descent method, which aims to reduce the MSE by following the steepest gradient on the error surface [4]. In a MLP, the output is function of the linear combination of hidden units activation, each of one is a non-linear function of the weighted sum of inputs. In this way, from equation 3:

$$y_j = f(x_j; \theta) + \epsilon$$

(3)

Where $x_j$ is the vector of explanatory variables, $\epsilon$ is the error component, $f(x_j; \theta) = \hat{y}$ is the unknown function to estimate from the available information, the network consist of equation 4:

$$\hat{y} = f(\nu_0 + \sum_{j=1}^{m} H(\lambda_j + \sum_{i=1}^{n} x_i w_{ij})v_j)$$

(4)

Where $\hat{y}$: Network output, $F$: Output layer activation function, $H$: Hidden layer activation function, $n$: Number of input units, $m$: Number of hidden units, $x$: Input vector ($i=1,\ldots,n$), $\theta$: Weight vector parameters, $\nu_0$: Output bias,
$\lambda_j$: Hidden unit bias ($j=1\ldots m$), $w_{ij}$: Weight from input unit $i$ to hidden unit $j$, $v_j$: Weight from hidden unit $j$ to output [6].

The activation function for output layer $F(x, w)$ might be a linear function of the inputs through the weights ($w$) plus a constant. After neural training (training set), new observations (validation and/or test sets) are presented to the network to verify the so-called generalization capability. Here it is relevant the statistical classical bias–variance dilemma [14] or overfitting problem [8].

2.2.2. ARTIFICIAL NEURAL NETWORKS AND EFFICIENCY MEASUREMENT

There are several approaches for performance measurement with ANNs. The neural network efficiency will be determined using the predicted values obtained from the solution to the model. Three basics approach herein are following:

1- An approach similar to ordinary least squares (OLS): In this approach the efficiency measure of a unit is established in relation to the average performance. Thus, the indicators will be superior to 1 or 100% when the unit behaves better than average and inferior to 1 or 100% if the unit is “inefficient”. These measures are not directly comparable with the traditional techniques. Reference [4] called this option “non-standardized efficiency” (Equation 6).

$$E^E_i = \frac{y_i}{\bar{y}_i} \quad E^E_i \text{ or } E^\text{MLPMAX}_i = \frac{y_i}{\bar{y}_i + \text{avg}(e_i)} \quad E^E_i = \frac{y_i}{\bar{y}_i + \text{avg}(e_i)}$$

To achieve a real production frontier there are some alternatives:

2- Shift the network by largest positive error: This option is similar to corrected ordinary least squares (COLS). The correction by the largest positive error is sensitive to outliers and the frontier will be deterministic. The efficiency scores take values between 0 and 1. This maximum score is assigned to the unit used for the correction. Reference [4] called this second measure “standardized efficiency” $E^E$ and [15] called this $E^\text{MLPMAX}$ (Equation 7).

In relation to DEA, the non-standardized efficiency ($E^\text{NE}$) tends to overestimate the indicators, and the standardized efficiency ($E^E$) tends to underestimate the measures.

3- Shift the network by a mean of the largest positive errors: this option is similar to modified ordinary least squares (MOLS). In this approach it is possible for a DMU to take efficiency greater than 1 (Equation 8).
2.3. DATA ENVELOPMENT ANALYSIS-ARTIFICIAL NEURAL NETWORKS

Reference [2] integrate Data Envelopment Analysis and Artificial Neural Networks and propose DEA-ANN as an algorithm that explained in follow.

2.3.1. ALGORITHM

1. Collect a data set S which describes the input-output relationship for DMUs. Obtain the preprocessed data set SS after the data in S are divided by an integer 1000 for the purpose of neural network training and simulation.

2. CCR method is used to calculate efficiency score of DMUs in S. The data set SS is grouped into four categories S1, S2, S3, and S4 based on the efficiency scores. The efficiency score intervals of S1 $\epsilon(0.98, 1]$ are referred as ‘strong relative efficient interval’. The efficiency score intervals of S2 $\epsilon(0.8, 0.98]$ are referred as ‘relative efficient interval’. The efficiency score intervals of S3 $\epsilon(0.5, 0.8]$ are referred as ‘relative inefficient interval’ and the efficiencies of S4 $\epsilon(0, 0.5]$ are referred as ‘very inefficient interval’.

3. Train neural network NN1 with S1 and any other two groups of data subset (e.g. S1$^\text{c}$S2$^\text{c}$S3 or S1$^\text{c}$S2$^\text{c}$S4 or S1$^\text{c}$S3$^\text{c}$S4). If the pre-specified epochs or accuracy is satisfied, STOP; go to Step 5. Otherwise, change one training subset and go to Step 3.

4. Apply the trained neural network model to the data set SS to calculate efficiency scores of all DMUs.

5. Post process the calculated efficiency scores by regress analysis between DEA-NN results and CCR DEA results. Do statistics analysis of DEA-NN efficiencies.

3. PERFORMANCE ASSESSMENT OF SADERAT BANK BRANCHES

1. Determination input ($x_i$) and output ($y_i$) variables of the model where $i=1,\ldots,n$ and $k=1,\ldots,l$

2. Collecting data set S in all available previous periods which describes the input–output periods which describes the input–output relationship for DMUs. Assume that there are a set of $j=\{1,\ldots,m\}$ DMUs to be evaluated. Note that the current period data ($S_c$) which evaluation will have been done on them, do not belong to S.

3. Divide S in to two subsets: training ($S_1$) and test ($S_2$) data.

4. Use ANN method to estimate relation between input ($x_i$) and output ($y_i$). For this reason follow these steps:
   - Select architecture and training parameters.
   - Train the model using the training data ($S_1$).
   - Evaluate the model using the test data ($S_2$).
   - Repeat these steps using different architectures and training parameters.
   - Select the best network architecture (ANN*) from the testing data error.

5. Run ANN* for $S_c$.

6. Calculate the error between the real output ($y_i$) and ANN model output ($\hat{y}_i$) in the period which you want to assess the efficiency of its DMUs ($S_c$):

   $\varepsilon_i = y_i - \hat{y}_i \quad i=1,\ldots,n \quad (9)$

7. For $DMU_j$, Measure the efficiency of outputs ($y_i$) with equitation (7).

8. Integrate the efficiency of outputs with AHP and acquire a single ranking for each DMU. Accordingly in follow a proposal algorithm was discussed

3.1. PROPOSAL ALGORITHM

- Assume outputs efficiency and DMUs as attributes and alternatives respectively.
- Plan a hierarchical structure similar figure 2. There are $m$ attributes and $n$ alternatives in the first level respectively.
Calculate a geometric mean \( (a_i) \) for output efficiency (equation 10).

\[
a_i = \left( \prod_{j=1}^{n} E_{y_{ij}} \right)^{\frac{1}{n}} \text{ where } i = 1, \ldots, m
\]  

Prepare Pairwise comparison matrices for attributes level (figure 3). It is obvious that proposal algorithm don’t require to judgments of decision makers.

\[
\begin{array}{ccccccc}
E_{y1} & E_{y2} & E_{y3} & \ldots & E_{ym} \\
E_{y1} & 1 & a_{1}/a_{2} & a_{1}/a_{3} & \ldots & a_{1}/a_{m} \\
E_{y2} & a_{2}/a_{1} & 1 & a_{2}/a_{3} & \ldots & a_{2}/a_{m} \\
E_{y3} & a_{3}/a_{1} & a_{3}/a_{2} & 1 & \ldots & a_{3}/a_{m} \\
& \vdots & \vdots & \vdots & \ddots & \vdots \\
E_{ym} & a_{m}/a_{1} & a_{m}/a_{2} & a_{m}/a_{3} & \ldots & 1 \\
\end{array}
\]

Prepare Pairwise comparison matrices for alternatives level.

Integrate two matrices and acquire final ranking of DMUs.

### 3.2. Case Study

In this study inputs and outputs are employees, terminals, capital and deposits, loans, profit respectively. Calculations related to DEA models and ANNs performed by use of EMS and MATLAB softwares. Final results are shown in table 2. This table shows efficiency scores and ranking earned by each method. Also it is obvious in figure 4 that every three methods have same trends in ranking.
A new approach in performance evaluation with Artificial Neural Networks

4. SUMMARY AND CONCLUSION

This paper analyses the efficiency of 66 Saderat bank branches in Iran by use of DEA, ANNs-DEA and a proposal algorithm namely ANN-AHP. Table 3 show spearman correlation coefficients between DMU ranks in different methods. Results show that proposal method (ANN-AHP) has satisfactory correlations with other method therefore ANN-AHP can introduced as an alternative approach in performance evaluation.

Design of a Framework for Inventory Control – Evaluation of Forecasting and Inventory Control Systems

Philip Hedenstierna, Per Hilletofth*, and Olli-Pekka Hilmola
Logistics Research Centre
School of Technology and Society
University of Skövde
541 28 Skövde, Sweden

ABSTRACT
Managing inventories so that overall costs are kept low, while service levels are maintained is the central issue of inventory control, which only regulates two things: the size and the timing of orders. This is typically executed through a planning method, such as the reorder point system or, less frequently, the periodic order quantity system. These take into account a forecast, supposed to gauge the average future demand, and a predetermined safety stock, buffering against forecast errors and demand uncertainty. Pure demand also influences the system, as transactions affect the inventory level. It is crucial to understand how a complete system of demand, forecasts, safety stock calculations and planning methods work together to measure service level and overall cost of the system. This paper outlines a framework for the unambiguous representation of the relations between methods that interpret environmental parameters to plan orders. A number of simulations based on the framework are run to show, how the integration of the inventory control functions may affect the overall performance of the system. The usefulness of the framework lies in its ability to make a system duplicable (i.e. to transfer an inventory control system to a simulation model, or vice versa). Not only is this property important for creating simulation models that exactly depict the system being analysed, it also enables the study of a complete system for order planning, as opposed to optimising individual methods. Studying an inclusive system allow the same metrics to be used to evaluate changes to any method in the system. Another benefit of this approach is that the system’s metrics directly reflect changes in the environment. Simulations based on this framework are precise and substantially easier to evaluate than models not adhering to any standard.

1. INTRODUCTION
The purpose of inventory control is to ensure service to processes or customers in a cost-efficient manner, which means that the cost of materials acquisition is balanced with the cost of holding inventory [1]. This balancing is done by interpreting data describing the planning environment, i.e. the parameters that may affect the decision, to generate replenishment order times and quantities [2]. The performance of an inventory control system may then be measured by the service and the total cost it generates when applied in a certain environment. Inventory control methods may be classified by whether they determine ordering timing, quantity, or both [3]. For systems that determine only one aspect, such as the reorder point system or the periodic ordering system, the aspect not determined by the system must be calculated beforehand, typically using the economic order quantity or the corresponding inventory cycle time, which enables the generation of order timing and quantity [3]. The parameters that inventory control systems are based on are a forecast of demand, expected lead times, holding costs and ordering costs. Of these, the forecast is of special concern, as it is not a part of the planning environment, but a product thereof. This makes forecasting, given our definition of inventory control, an integral part of the inventory control system. To maintain service when there is forecast and lead time variability, a safety stock mechanism is used, which is based on measures of variability and on the uncertain times that come with the used inventory control model [4]. As the safety stock incurs a holding cost, it may be argued that it should be part of the timing/sizing decision, but it is usually excluded as the cost savings gained from optimisation generally are insignificant [5].

* Corresponding author: Tel.: +46 (0)500 44 85 88; Fax: +46 (0)500 44 87 99; E-mail: per.hilletofth@his.se
We have now discussed three interdependent areas that are usually treated as individual entities. They are all part of generating replenishment orders by interpreting the planning environment, and may consequently affect the performance measures of the system. The current approach to inventory control does generally not consider it as a single system, but as separate methods (see e.g. Axsäter [5], Waters [4], Mattsson & Jonsson [3] and Vollman et.al [6]. An exception is Higgins [7], who describes inventory control as a process (see Figure 1), but does not detail show information flows through the model, nor does he isolate the functions of forecasting, safety stock sizing and inventory control.

![Diagram of the inventory control process](image)

**Figure 1. Higgins’ model of the inventory control process** [7].

Looking at Higgins model, it is easy to realise that corruption of data occurring in an operation or between operations will cause the incorrect data to affect the subsequent operations (see Ashby [8]). When theoretical models are applied to scenarios that follow the assumptions of the models, this is not an issue; but when a model is applied to a scenario it is not designed for, data corruption ensues. Applied to inventory control, this may mean that a simple forecast or a simple inventory control method is applied in an environment that does not reflect the method’s assumptions. When a method’s assumptions are unmet, its performance may be difficult to predict. The scenario of using theoretically improper methods is not unlikely, as businesses may want to utilise inventory control methods that are simple to manage, such as the reorder point system, even when the environment would require a dynamic lot-sizing method such as the Wagner-Whitin, part-period or the Silver-Meal algorithm (see Axsäter [5]). In the same fashion, simple forecasting methods may be applied to complex demand patterns for the sake of simplifying the implementation and management of the forecasts. To understand how a method will respond to an environment it was not designed for, it is necessary to understand the entire process, from planning environment to measurement of results. As it may be difficult to predict how a system based on a required type of input will react to non suitable data, a model of the system may help to give insight into the system’s performance. Ashby [8] states in his law of requisite variety, that a regulatory system must have at least as much variety as its input to fully control the outcome; applied to the inventory control process, this effectively means that all aspects of a system must be modelled to give an accurate result. Inventory control systems consist of a three types of methods; forecasting, safety stock sizing and order timing and sizing [5]. Though there are many individual methods, only one method of each type may be employed in an inventory control system for a single stock-keeping unit.

The research objective of this study is to provide an increased understanding of the following research questions: (1) How may the process of inventory control be described unambiguously in a framework that allows for any combination of methods to be used, and (2) Is there any benefit to treating inventory control as a process, rather than as individual methods? This paper describes how complete inventory control systems can be modelled by using a framework that maps all relations from planning environment to performance measures. The unambiguosity means that a model designed for simulation purposes can be transferred to a real-world implementation without loss of functionality. It also means that single parts of inventory control systems can be modified, so that a better understanding of how a specific part contributes to the overall performance of the system may be gained. The structure of this paper is as follows: First, Section 2 describes the research approach. Thereafter, Section 3 integrates existing theory to describe a framework for designing inventory control models. Section 4 introduces empirical data from a company, of which the planning environment was used in Section 5 to develop a simulation model based on the framework. Section 6 describes the results of simulations of individual methods, and one simulation based on the framework. After that, Section 7 discusses the implications of the results, while Section 8 describes the conclusions that can be drawn from the study.

2. RESEARCH APPROACH

The design of the framework was based on a literature review of inventory control theory and on the authors’ experience of the area. Simulations were run for two reasons: One was to simulate inventory control systems for planning environments that were either following, or not following the assumptions of the simulated method; this
Design of a Framework for Inventory Control – Evaluation of Forecasting and Inventory Control Systems

tests whether the system performance changes when a foreign planning environment is introduced. The other reason to simulate was to see if the framework could be of practical use when employed to help a case company decide on a for their planning environment appropriate inventory control solution.

3. DESIGN OF AN INTEGRATED FRAMEWORK

The design of the framework is based on observing how inventory control methods operate, what input the methods require and what output they give. The underlying assumption for inventory control systems is that there for any given time \( t \), is an inventory level \( LL_t \), which is reduced by demand \( D \) and increased by replenishment \( R \). Another assumption is that time is divided into buckets (as described by Pidd [9]), for continuous systems buckets are infinitesimal, and that for each bucket the lowest inventory level, which is sufficient to evaluate the effects of inventory control, is governed by Formula 1. The relationship between these factors has been deduced from the rules that material requirements planning is built on [6].

\[
LL_t = LL_{t-1} + R_{t-1} - D_t \quad \text{subject to } LL_t \geq 0
\]  

(1)

where, \( LL_t \) = lowest inventory level at time \( t \), \( R_{t-1} \) = replenishment quantity occurring before \( t \) and \( D_t \) = demand during \( t \).

Formula 1 is the law that dictates how the transactions of any system placed in the framework will operate. It considers replenishment to occur between time buckets, meaning that it is sufficient to monitor the lowest inventory level for the law to reflect inventory transactions. Information such as service levels, inventory position and the highest stock level may be calculated from the lowest inventory level. The formula governs the inventory transactions of any inventory control system, and must be represented in any inventory control application. All other parts of an application may vary, either depending on the planning environment in which an inventory control system is used, or on the design of the system. Figure 2 shows the framework, which starts with the planning environment and ends with a measurement of the system’s performance.

Figure 2. Framework describing relations within inventory control systems.

The planning environment comprises the characteristics of all aspects that may affect the timing/sizing decisions [2]. For each time unit, the environment, which determines the distribution of demand, generates momentary demand that is passed on to a forecasting method, to an inventory control method and to actual transactions. The type of demand, which is dictated by the planning environment, tells whether a backlog can be implemented or not, and what function that may represent it [4]. Forecasting is affected by past demand information and the planning environment [1]. The former is used to do time series analysis, which is common practice in inventory control, while the latter may concern other input, such as information that may improve forecasting or data needed for causal forecasting. The environment may also tell of changes in the demand pattern, which may necessitate adjusting forecasting parameters.
or changing the forecasting method. It is necessary to consider the aggregation level of data, as longer term forecasts will have a low coefficient of variation, at the cost of losing forecast responsiveness [6]. Data from forecasting is necessary for inventory control methods (forecasted mean values), and for safety stock sizing (forecast variability) [3]. Safety stock sizing is a method which buffers against deviations from the expected mean value of the forecast [4]. The assumption of safety stock sizing is that all forecasts are correct estimations of the future mean value of demand; any deviations from the forecast are attributed as demand variability. This effectively means that an ill-performing forecast simply detects higher demand variability than a good forecast. The sizing is also affected by the planning environment, as the uncertain time determines the need for safety stock, as lead times also may have variability, and as the environment will determine to what extent customers accept shortages, or low service [1].

Inventory control methods rely on forecasts, on safety stock sizing and on the planning environment. The safety stock is used as a cushion to maintain service, while forecasts and data from the planning environment, which are ordering costs, holding costs and lead times, are used to determine when and/or how much to order [6]. The actual balancing of supply, which comes from the replenishment of the inventory, and demand, which is sales or lost sales, takes place as inventory transactions. Measuring these transactions gives an understanding of how well an inventory control system performs for the given planning environment [4].

4. EMPIRICAL DATA

Data was collected from a local timber yard, which did not use any policy to manage its inventories. Because of built-in ERP functionality for the reorder point method and for the periodic order quantity method, these methods could be deployed at low cost. The question was if the methods could cope with the demand for timber, which was presumed to have trend and seasonal components. Based on an analysis of sales data, the demand for timber was found to be seasonal, but with no trend component. This information was used to generate a demand function, based on the normal distribution, for the simulation model. The purpose of the demand function was to allow the simulation model to run for longer periods of time (5 years). Real demand, as well as simulated, is shown in Figure 3.

![Figure 3. Simulated demand compared to actual demand.](image)

Demand characteristics are shown in Table 1 and other parameters pertaining to the planning environment are shown in Table 2.

<table>
<thead>
<tr>
<th>Demand</th>
<th>Year</th>
<th>Month</th>
<th>Day</th>
</tr>
</thead>
<tbody>
<tr>

<td>710</td>
<td>205</td>
<td>37</td>
</tr>
<tr>
<td>( s(\sigma^2) )</td>
<td>504100</td>
<td>42025</td>
<td>1369</td>
</tr>
</tbody>
</table>

As transport costs were considered to be semi-fixed rather than variable, the reordering cost is valid for the reorder quantity used. Increasing the order quantity was not a cost-effective option. Stock out costs were not considered, as the consequences of stock outs are hard to measure; not only are sales lost, there is also the possibility of competitors winning the sale, and of losing customers, as they cannot find what they need.
Table 2. Environmental parameters.

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lead time (days)</td>
<td>7</td>
</tr>
<tr>
<td>Order cost (SEK)</td>

<td>4.49</td>
</tr>
<tr>
<td>Order quantity (units)</td>
<td>585</td>
</tr>
<tr>
<td>Order interval (days)</td>
<td>45</td>
</tr>
</tbody>
</table>

Lead times are considered as fixed, as no information on delivery timeliness was available. The expected cost for non-seasonal demand, assuming that no safety stock is used, would be 25 659 SEK for both the systems, with an expected fill rate of 98% for the reorder point method, while the fill rate for the periodic order quantity method would be 95% (calculated using the loss function, as described by Axsäter [5].

5. DESIGN OF A SIMULATION MODEL

To test how the framework could be applied to a real-world scenario, a simulation model was constructed with the purpose of evaluating inventory control solutions that were considered for implementation by a local timber yard. To support the inventory control systems, some simply managed forecasting systems were chosen as alternatives that may fit the inventory control solution. The combination of forecasting methods and inventory control methods, put into the context of the framework is shown in Figure 4.

All methods were verified against theory individually by testing if the method implementations gave the values that theory would dictate. Because of the time bucket sizing (days), undershoot of the reorder point occurred for the reorder point method; to handle this condition the reorder point was increased by ½ days of forecasted demand as suggested by Mattsson [10], granting near-theoretical performance of the method. Though several forecast methods were considered, the actual choice of forecast for the case company’s demand pattern was based on an evaluation of the mean absolute deviation. The mean deviation was also calculated to see whether a forecasting method followed the mean of demand accurately. Comparative results are shown in Table 3. The seasonally adjusted moving average (see Mattsson and Jonsson [3]) was chosen as the preferred method as it proved to be nearly as accurate as Holt-Winters method (see Axsäter [1]), while not requiring as careful calibration of the forecast parameters. Forecasts were monthly, and predicted the demand for the following month. The forecast value was multiplied by 1.5 to reflect
an economic inventory cycle time of 45 days. This simplification was done to see how the system would react to systematic design errors in the application of the forecast.

<table>

6. Simulation runs

To investigate how seasonality may affect the performance of simple planning methods, three different demand patterns with increasing complexity were simulated. In the first, demand was constant and without variance, in the second, variance was added, while in the third, light seasonality (±20%) was introduced. Each simulation was measured 5 consecutive years (runs), with stable behaviour observed through all years. Table 4 shows the values used for demand. A lead time of one day was used, while the order quantity was 900 with the corresponding interval 15 days.

<table>
<thead>
<tr>

<td>s (σ²)</td>
</tr>
</tbody>
</table>

The forecast was fixed to reflect the yearly average in all three cases, meaning that the framework was bypassed to ensure that only the effect of seasonality on the methods would be measured. Ignoring safety stock altogether, the measures used for the simulations were fill rate and inventory cycle service level. Figure 5 shows the results for the three demand types.

![Inventory cycle service level and Fill rate](image)

Figure 5. Cycle service levels and fill rates.

What can be seen is that inventory cycle service is higher for the periodic order quantity method, while the reorder point method has a higher degree of inventory cycles with stock-out. However, the fill rate shows that the reorder point method is the best at fulfilling demand. Together, the measures tell that the periodic order quantity method has fewer, but significantly greater stock-outs than the reorder point method. Seasonality affects the severity of the stock-outs for the periodic order quantity method, but not for the reorder point method, which manages the variations in demand by shortening the inventory cycle time. We may therefore conclude that seasonality can have a noticeable effect on methods that are not designed for such demand patterns.

In contrast with the above simulations, the one which used information from the case company was based on the framework, integrating forecasts and inventory control methods. The result of the simulation is shown in Figure 6, which is based on fill rate and the total yearly cost of the inventory policy. The periodic order quantity system shows a considerably worse fill rate than the reorder point system, though the safety stock is sized so that both methods should have the same fill rate if demand were non-seasonal.
Design of a Framework for Inventory Control – Evaluation of Forecasting and Inventory Control Systems

7. DISCUSSION

The simulations indicate that the fill rate of the periodic order quantity method suffers when a seasonal demand pattern is introduced, while the reorder point method can maintain the same fill rate as if no seasonality were present. This is a result of the nature of the two methods, where variability affecting the reorder point method will affect the time of ordering, while the periodic order quantity method, with fixed ordering times, cannot regulate order timing to prevent stock outs. Instead, it must let the inventory level take the full effect of any variability. Conversely, the effect of variability on the reorder point method is that the resulting order interval may not be economic. Uneconomic order quantities are not always a severe problem, as shown by Axsäter’s investigation of less-than-optimal order quantities.

When comparing the methods used in the timber yard simulation using the framework, we find that the reorder point method is superior both concerning the safety stock costs, and the fill rate. The extremely low fill rate (77%) demonstrated by the periodic order quantity shows how inventory control methods that are unsuitable for the planning environment can be affected. The use of a monthly forecast not representing the next inventory cycle may also have contributed to the low fill rate. The simulation based on the framework helped give insight into how the inventory control process would react to the planning environment. It showed that a large safety stock would be required if the periodic order quantity were to be used. If applied over multiple products, the framework can tell if consolidation using the sensitive periodic order quantity system is less costly than the insensitive reorder point system. Given that the periodic order quantity system has a 100% uncertain time [1], it may be used as a benchmark in simulations, as variability and problems caused by poor design of the process always will be reflected in the fill rate. This means that efforts to improve an inventory control process can be tested using this method.

In the future we are planning to enlarge our simulation experiments by incorporating different kind of demand types (continuous and discontinuous) as well as new methods used in forecasting and ordering. Recent research works have shown that autoregressive and particularly GARCH forecasting methods outperform others in situations, where demand is fluctuating widely and has clearly “life-cycle” pattern [11]. Similarly recent purchasing order method research has argued that not a single ordering method should be used (so basically it is not a question, which method is the best one, but which one is most suited to certain environment), but usually combination of different purchasing methods should be incorporated in ERP systems during the entire life-cycle of a product [12]. However, if volumes are low, then even economic order quantities/reorder point systems, and periodic order policies should be abandoned; lot for lot policy might produce best results in these situations [12]. Thus, much depends from the operations strategy (order or stock based system), and from the amount of time, which customers are willing to wait for a delivery to reach their facilities [13].

8. CONCLUSIONS

Treating inventory control and forecasting as separate activities, while not acknowledging how forecasting and its application may affect inventory control may lead to incorrect assessments of a system’s performance in a certain planning environment. Approaching inventory control as a process that starts with a planning environment and ends with a measurement of the system’s performance shows that all activities are related, and that the end result may be affected by the activities or by the way they are connected. In this paper a simulation model was built, to show how
the framework could be implemented, and simulations were run. It was shown, that using the framework to design an inventory control process enables different systems to be compared, and gives measures of how a complete inventory control process performs. Using the framework to design simulation models for testing a system for a planning environment will give a clearer view of how the system will react, than if forecasts and inventory control methods were evaluated alone. Describing the activities and the connections presented in the framework gives a complete system that may be implemented exactly as described. Documenting a system in this manner, enables transfer from simulation models to real inventory control applications or vice versa. Using simulation models to evaluate changes to the planning environment, or a change in the methods used is also easily done, due to the modular design of the framework.

Optimizing Product Placement for Manual Picking in Warehouses

Uday Venkatadri and Sachin Kubasad

1Department of Industrial Engineering
Dalhousie University
Halifax, Nova Scotia, B3J 2X4, Canada

ABSTRACT

This paper looks at the problem of optimal product placement for a rectangular manual picking area in a warehouse, motivated by a practical industrial case in the food and beverage industry. In this paper, we compare the operational implication of three heuristic product placement strategies for two types of layouts: one with dead-end aisles and the other with open ended aisles. Our results show that open-ended aisles result in less travel distance, which agrees with intuition. We did not find appreciable differences in the performance of the three assignment heuristics; they all seem to be good. However, it is important to note that certain assumptions were made in this paper in obtaining these results.

1. INTRODUCTION

It is well known that improving the product placement in a warehouse can lead to gains in productivity in the picking operation. We consider the problem of optimal product placement problem for a rectangular warehouse in which picking is done manually by an order picking crew which uses a predetermined picking route. We also assume that the picking is done for one (usually large) order at a time.

This problem has practical importance; for existing warehouses, it is important to know the savings that can result from a combination of improved aisle design and product placement. For new warehouses, the question is how to lay out the aisles and place products.

Our involvement in this was motivated by a practical industrial case in the food and beverage industry. A section of a company’s distribution centre (DC) came under review. The company wanted to know if the product placement could be improved. From the aisle design point of view, the section in question at the DC had dead-end aisles. We believed that this was resulting in higher total travel for picking. We were interested in looking at the impact of changing the aisles so that each picking aisle was accessible from either end.

From an aisle design perspective, we look at both open-ended aisles and dead-end aisles.

From a product placement point of view, we identified three heuristics that are commonly used in rectangular warehouse sections:

- Place products in a zig-zag manner along the aisles in decreasing order of annual volume to match the S-Shaped heuristic picking route commonly employed in practice (N-S heuristic),
- Place products in decreasing order along aisles, starting with the aisle closest to the picking origin (N-N heuristic), and
- Place high volume products as closely as possible to the origin (nearest location heuristic).

We first discuss the main results in the literature dealing with product placement in manually picked warehouses. We will then report on the results of our study in which we evaluated combinations of product placement heuristics and aisle for the practical problem.

2. RELEVANT LITERATURE

Gu et al. [1] present an excellent review of papers on warehouse operations. The framework presented in the paper essentially consists of two large blocks: warehouse design and warehouse operations. The two blocks are shown to then interact with each other with a bi-directional link. In other words, warehouse operations are affected by its design and vice versa.
Hall [2] looks at three strategies for picking in a simple rectangular warehouse: traversal, midpoint, and largest gap. He then develops approximations for expected travel distance for each of these picking strategies. In all cases the author considers open-ended aisles. In the traversal strategy, once picking starts on an aisle, the entire aisle is traversed. In the midpoint strategy the aisle is broken into two halves and the halves are accessed from either end. It is used when an aisle contains less than one pick. The largest gap strategy is similar to the midpoint strategy, except that the order picker enters as far as the largest gap between two adjacent picks. For each of these strategies, the author develops formulas for expected pick lengths. One assumption in the paper is that the picking locations are randomly distributed, independently and uniformly through the warehouse. This assumption is a restriction for dedicated warehouses, including the one we were interested in.

Roodbergen et al. [3] present an eleven-component estimate for travel distance estimation in warehouse picking operations. Their estimate is based on warehouses with any number of rectangular blocks assuming that the S-shaped heuristic is used for routing. However, random storage is assumed in this paper. They then compare the performance of their travel distance estimate with simulation and report that the average error compared to simulation for a test set of 320 layout problems is 0.3% for the S-shape heuristic with a maximum error of 2.9%.

Another relevant article to this research is the one by Sadowsky and Ten Hompel [4], who use an analytical method to calculate travel distance. They assume that the access frequency distribution from the front of an aisle is known. For example, this distribution could follow the exponential distribution, such that the probability of picking along the aisle is exponentially distributed as a function of the distance. One assumption of this study is that all aisles have the same access frequency.

Based on these papers in the literature, we concluded that a new model for estimating travel distance was necessary in our case to take into account the following aspects in combination:

- Random storage is too restrictive as an assumption. In our problem, the storage locations are dedicated because of the choice of technology and a desire for simplicity.
- The frequency of accessing the aisles could be different since the assignment of products to aisle is a decision variable for the warehouse planner.

2. Layout Structure

As mentioned earlier, we look at two types of layouts in this paper – one with open-ended aisles (Figure 1) and the other with dead-end aisles (Figure 2). We assume that the racks are structured in a block with a depot located at the bottom left. All picking routes begin and end at the depot. We also assume that the aisle length is much larger than the rack width as well as the spacing between aisles, such as the one between Racks 2 and 3.

![Figure 1: Open-ended aisle configuration allowing picking access from both ends](image)
In the configuration shown in Figure 2, an aisle may only be accessed one way. Once picking is completed along an aisle, the picker must backtrack along the aisle before the next pick.

Apart from the configuration of the aisles, products need to be assigned to them. We consider dedicated storage in this paper. While it is possible to develop optimization models for product assignment, we used three simple heuristics. The N-S assignment is shown in Figure 3. In this assignment, the highest volume products are allocated along Rack 1 in the northerly direction followed by Rack 2 in the southerly direction and so on. In this and all other heuristics, we do not allow product segmentation. In other words, the assignment of a product is such that it cannot be assigned to two aisles. Let us consider the example in which four products have been assigned to Rack 1. The fifth product cannot be assigned to Rack 1 because the number of remaining slots in the aisle is smaller than what is required for product storage. The product is then assigned to Rack 2 in a southerly direction. If the sixth product can be fit in Rack 1, the assignment is made, if not, assignment continues on Rack 2.

![Figure 2: Dead-end aisle configuration allowing picking access from only one end](image)

The N-N heuristic is shown in Figure 4. With this heuristic, products are assigned in a northerly direction across all aisles. This procedure results in decreasing product demands along racks which is an assumption in Sadowsky and Ten Hompel [4]. However, the expected probability of accessing an rack decreases with the rack number.

![Figure 3: N-S product assignment heuristic](image)
The third and last heuristic considered in this paper is the nearest location heuristic (Figure 5). Here, products are first sorted in descending order of volume. The slots are sorted in ascending order of distance from the depot. The first product in the product list is assigned slots starting with the closest slot in the slot list where the assignment results in the allocation of product to continuous slots within a single rack. The product is dropped from the product list and the slots from the slot list and the procedure continues.

In the example illustrated in Figure 5, products P1, P2, and P3 are in decreasing order of volume. Therefore, P1 is first assigned to the slots indicated. P2 is then assigned to slots starting with the closest available slot, which is the third slot in Rack 1. P3 is assigned next and this process continues. If P2 could not have been fit on Rack 1 because of the number of slots remaining in the rack after assigning P1, the assignment would have started in the first slot of Rack 3 (where P3 is shown to start).
2. DISTANCE APPROXIMATIONS

In this section, we develop distance approximations for the two configurations shown in Figures 1 and 2.

2.1. OPEN-ENDED CONFIGURATION

For the open-ended aisle configuration, we assume that once the order picker enters the aisle, the entire aisle is traversed. Obviously, this is a simplifying heuristic which does not take into account backtracking from an aisle depending on which aisle is entered next and where the next pick occurs.

Let the probability of entering aisle $j$ be $P(j)$. Let $Q$ be the set of all products and $Q_j$ the set of products in aisle $j$. Let $D_i$ be the demand rate of product $i$. The aisle is entered if any of the products in the aisle is required. Therefore:

$$P(j) = \prod_{k \in Q_j} (1 - \sum_{i \in Q} D_i)$$ (1)
Figure 7: Probability tree of traversal path for the open-ended configuration

Figure 6 shows the critical locations reached in a complete picking path. For the twelve rack configuration shown in the figure, there are 13 locations numbered 0, 2, … 12 for convenience. Once the picker starts at the depot, he or she has two choices; if Rack 1 needs picking, the picker ends up in location 0c (where c denotes ‘complete’); else, the ending location is 1i. In the former case, the destination node of the picker is labeled 0c because aisle A has been picked at this point. We label the destination node of the picker in the latter case as 1i (i stands for ‘incomplete’) because at this point, racks 2 and 3 (along aisle B) are not yet picked. Obviously, after picking along rack 1, the picker may go back to the start location or move to 2i (when location 2 is reached in this manner, the aisle in front has not been picked and hence the location is labeled 2i). Location 2 may also be reached from location 1 after picking on racks 2 and 3 (along aisle B) and in this case, we label the destination node 2c (where c denotes ‘complete’). In this manner, it is possible to build the entire probability tree of the picking path (refer to Figure 7). In Figure 7, P(E) represents the probability of entering the corresponding aisle and P(NE) represents the probability of not entering the aisle (the probabilities are calculated from Equation 1). Also, the depot location S is shown on both the left and right sides of the tree for the purpose of convenience.

Since the distances are known for each location, it is possible to estimate the expected distance by reducing the tree. From S, two locations are possible, 1i and 0c. P(S-1i) is the probability of going from the depot (location S) to location 1i. The expected distance contribution along this path is P(S-1i)D_{S,1i}, where D_{S,1i} is the distance from S to 1i. From 1i, it is possible to go to 2c or 3i and from 0c, S or 2i are the only possible nodes. The expected distance for the entire picking path can be calculated by first finding the probability of entering a node in Figure 1 and multiplying it by the probability of each arc going out of the node and the distance along the arc.

2.1. DEAD-END CONFIGURATION

For the dead-end configuration, we calculate the expected depth of traversal into each aisle. This is given by:

\[ ED(j) = 2 \times \frac{\sum_{k \in Q_j} CD_{kj} D_k}{\sum_{k \in Q_j} D_k} \]  \hspace{1cm} (2)

Here, \( ED(j) \) is the expected travel distance along aisle \( j \). \( CD_{kj} \) is the distance to the centroid of product \( k \) along the aisle. As before, \( D_k \) is the demand rate of product \( k \) which is stored in aisle \( j \). We then assume that the picker travels along the cross aisle step by step and enters each picking aisle and returns to the cross aisle, as necessary.
The traversal path for the dead-end configuration is shown in Figure 8. In this configuration, there are seven critical locations numbered 1, 2, 3, …, 7 for convenience. The aisles have been renamed A, B, C, …, G. The order picker begins a route at the depot and reaches location 1. At this point, there are two possibilities. If there are items to be picked in aisle A, the traversal distance along aisle A (in and out) is calculated using the formula in Equation 2. If not, the picker simply continues on to location 2. If aisle A is traversed, the picker may either go back to the depot or continue on to location 2. This depends on whether there are items to pick in aisles B, C, D, …, G. Equation 1 is used to calculate the probability of entering any one of these aisles. From this basic equation, the probability of entering any of these aisles may also be calculated. The probability tree for dead-end travel is shown in Figure 9. The expected travel distance is computed by multiplying the node probabilities by the arc probability and distance. This computation is very similar to that of the open-ended case, the only difference being the probability tree itself.

![Figure 8: Critical locations in picking path for the dead-end configuration](image1)

![Figure 9: Probability tree of traversal path for the dead-end configuration](image2)
3. RESULTS

We used the distance approximation calculations developed in this paper to look at placement strategies for an anonymous industrial partner’s distribution centre. There were 854 products for assignment in a rectangular section of the DC with the same number of racks and aisles as shown in Figure 6. However, the depth of the racks and aisles were different - there were a total of 933 storage locations in the example with two pallet storage in each location. The demand of products varied significantly. With slot locations proportional to annual demand, the number of slots required for each product varied from 0.3 to 54.7. We assumed that the number of slots required could be fractional, allowing more than one product to share a slot location. In the configuration, the aisle widths were 2.74m with the racks themselves being 51.5m. Picking always takes place at the floor level locations, even though storage is 3 levels high. Table 1 below shows the distance approximation calculation results.

Table 1: Distance Approximations (metres)

<table>
<thead>

</tr>
</tbody>
</table>

As can be seen from the table, the nearest-location performs best overall when the open-ended configuration is used. However, there is very little difference between this and the other heuristics. In fact, the worst heuristic for this case is the N-S heuristic, whose performance is only 1.93% worse than the nearest-location heuristic. Our speculation is that the nearest-location heuristic keeps the location of frequently picked products as much as possible to the bottom and to the left (i.e., towards the depot). Therefore, it might result in the least expected distance. Our assumption is that the entire aisle is travelled when entered in the case of the open-ended configuration. This is obviously an oversimplification. We are in the process of examining what happens if the aisle can be broken up into two or more partitions to improve the distance estimate.

From Table 1, it can also be seen that the dead-end configuration results in much higher expected travel than the open-ended configuration. For example, in the N-N case, the performance degradation is 52.38%. For the dead-end configuration, the nearest location heuristic provided the least expected travel. We believe again that this heuristic keeps frequently visited products as close as possible to the depot, possibly the main reason why it is the best. The differences in performance between the three heuristics are appreciably more than in the open-ended case. The main benefit to the industrial partner from this study was that we were able to show them that it is better to use the open-ended configuration, though it requires slightly more space. By opening up the aisles, we expect that they will be able to improve their picking efficiency by at least 36%.

4. CONCLUSIONS AND FURTHER STUDY

Optimizing product placement has very important implications for picking operations. In this paper, we tried to build a costing model to look at the impact of three product placement heuristics on two different aisle configurations. It is clear that the open-ended aisle configuration results in less expected travel. However, our research is still in progress. The calculation of expected distance needs to be refined in many ways, especially for the open-ended configuration. We assumed in the open configuration model that once an aisle is accessed, it is traversed completely. This is not true. Depending on which products need to be accessed in the next aisle, it may be better to backtrack. We are in the process of modeling this further. We are also trying to build a simulation model to gain more insights and improve our expected distance calculations. Finally, we are interested in looking at how cross aisles may help improve picking efficiency.
ACKNOWLEDGEMENTS

The support made available to Uday Venkatadri through the National Science and Engineering Research Council of Canada’s Discovery and Equipment grants programs is greatly appreciated. Thanks are also due to an anonymous industrial partner who provided the data for the analysis done in this paper.

An exact approach to minimize the sum of maximum earliness and tardiness in single machine scheduling problem with sequence-dependent setup time

Nooshin Nekoiemehr* & Ghasem Moslehi

Department of Industrial and Systems Engineering,

Isfahan University of Technology,

Isfahan, 84156-83111, Iran.

Abstract

This paper considers the problem of scheduling a given number of jobs on a single machine to minimize the sum of maximum earliness and tardiness when sequence-dependent setup times exist \( (1|\text{ST}_{sd}|\text{ET}_{\text{max}}) \). This scheduling problem in view of trying to minimize the values of earliness and tardiness, can be applied in different production systems such as just in time (JIT) systems. Though considering sequence-dependent setup times increase the complexity of the problem significantly, is often encountered in different production systems. In this paper an optimal branch and bound algorithm is developed including the implementation of lower and upper bounding procedures, and dominance rule. For solving problems containing large number of jobs a polynomial time-bounded heuristic algorithm is also proposed. The proposed algorithms were empirically evaluated on 3840 problems of various sizes, ranging from 8 to 25 jobs, and different parameters. Computational experiments demonstrate the effectiveness of the bounding rules in achieving optimal solutions in more than 97% percent of the instances.

1. Introduction

In this paper, we address the problem of finding an optimal solution of \( n \) jobs with sequence-dependent setup times to minimize the sum of maximum earliness and tardiness on a single machine; the problem is shown as \( (1|\text{ST}_{sd}|\text{ET}_{\text{max}}) \). Interest in scheduling problems that treat setup times (costs) as separate began in the mid-1960s [1]. The importance of setup times has been investigated in several studies. Panwalkar [2] found about three quarters of the managers in his survey reporting that at least some operations they scheduled required sequence-dependent setup times, while approximately 15% reporting all operations required sequence-dependent setup times [1]. Scheduling problems with sequence-dependent setup times are often encountered in many production systems and industrial applications including color procedure in the plastic industry [3], wafer testing in semiconductor manufacturing [4], and in photocopiers and laser printers [5]. Allahverdi et al. [1] surveyed the literature on separate setup times involving static, dynamic, deterministic, and stochastic problems for all shop environments including single-machine, parallel machines, flow shops, job shops, open shops, and others.

Wisner and Siferd [6] reported that meeting target delivery dates was the most important scheduling objective and only 58% of industrial schedulers managed to meet delivery dates. As declared by Luh et al. [7], “the understanding of sequence-dependent setups, however, is still believed to be far from being complete, especially of scheduling to meet due dates”. Meeting due dates while also considering both tardiness and earliness is important. A number of authors have addressed problems involving due dates and sequence-dependent setup times in order to minimize sum of earliness and tardiness. Baker and Scudder [8] provide a survey of sequencing problem with earliness and tardiness penalties while Kanet and Sridharan [9] provide a review of scheduling with inserted
In the remainder of the paper, \( \sigma' \) refers to the set of jobs that are not scheduled. Job \( \sigma(j) \) is defined as a partial schedule and \( \sigma' \) as a set of jobs that are not scheduled. Job \( \sigma(j) \) itself, whereas job \( \sigma(j) \) (with brackets) refers to the job \( j \) itself. In the remainder of the paper, \( \sigma \) is assumed that all jobs are available from time zero and the machine has no predefined initial setup setting whatever the first task is. In addition, The triangle inequality is satisfied; in other words, among the setup times jobs \( i,j,k \), the inequality \( s_{ij} + s_{jk} \geq s_{ik} \) is applied. In a single machine scheduling, earliness \( (E_j) \) and tardiness \( (T_j) \) of job \( j \), maximum earliness \( (E_{max}) \), maximum tardiness \( (T_{max}) \), and the sum of maximum earliness and tardiness \( (ET_{max}) \) in each sequence are obtained as follows:

\[
E_j = \max(0,d_j - C_j), \quad j = 1,...,n
\]

(1)

\[
T_j = \max(0,C_j - d_j), \quad j = 1,...,n
\]

(2)

\[
C_j = \begin{cases} 
0 & j = 0, \\
\sum_{k=1}^{j} (s_{k-1} + p_k) & j \neq 0.
\end{cases}
\]

(3)

\[
E_{max} = \max_{1 \leq j \leq n} \{E_j\},
\]

(4)

\[
T_{max} = \max_{1 \leq j \leq n} \{T_j\},
\]

(5)

\[
ET_{max} = E_{max} + T_{max}.
\]

(6)

Although \( ET_{max} \) is a non-regular measure and it may be possible to reduce the objective by inserting idle time into a schedule, we assume that no idle insert is allowed as already mentioned in our assumptions above.

### 3. Branch-and-Bound Algorithm
To find the optimal sequence, we propose a branch-and-bound implicit enumeration approach for the problem of \( |ST_{ad}|ET_{max} \), the proposed branch-and-bound algorithm involves back-tracking rule as an branching procedure and each sequence is constructed by starting from the beginning and working forward so a node at the \( K \) level in the B&B tree corresponds to a partial sequence for the first \( K \) jobs in a sequence, \( \sigma = J_1 \ldots J_k \).

### 3.1. LOWER BOUND

In order to develop a lower bound for the problem of \( |ST_{ad}|ET_{max} \), a lower bound is initially described in lemma 1 for the problem of minimizing the sum of maximum earliness and tardiness without setup times (\( |J|\}) \) ET_{max}). Then, based on the procedure presented by Schaller, lower and upper bounds are proposed on the completion times of unscheduled jobs by means of setup times \([17,22]\). Next, these bounds are employed in a mathematical program whose optimal solution provides a lower bound for the problem of \( |ST_{ad}|ET_{max} \).

Let \( \text{d}_{\text{EDD}}[j] \) equal the due date of the \( j \)th job. If the jobs are sorted according to the earliest due date (\( \text{d}_{\text{EDD}}[j] \leq \text{d}_{\text{EDD}}[k] \) if \( j < k \)) and if the completion times of the job in each position of a sequence are known, then a lower bound is obtained on the sum of maximum earliness and tardiness without setup times from the following theorem.

**Lemma 1.** If the completion time of the jobs in each position of a sequence is known, \( LB \) is the lower bound for the problem \( |J|\}) \) \( ET_{max} \). Where, \( C_{[ij]} \) is the completion time of the job in \( j \)th position of the sequence.

\[
LB = \max \left( \max \left( C_{[ij]} - \text{d}_{\text{EDD}}[j],0 \right) \right) + \max \left( \max \left( \text{d}_{\text{EDD}}[j] - C_{[ij]},0 \right) \right)
\]

**Proof.** Consider a schedule \( S \) in which the job at the sequence position \( j \) has a due date greater than the due date of the job in the sequence position of \( k \), where \( j < k \), if \( d_0[j] \) and \( d_0[k] \), respectively, are the due dates of the jobs in the sequence positions \( j \) and \( k \), then \( d_0[j] < d_0[k] \). Now consider another schedule \( S' \) obtained by interchanging due dates of these two jobs in these positions. In other words, \( S' \) is obtained by assigning the due date of the job in position \( k \) to that in position \( j \) and vice versa. Therefore, the completion times for the jobs in all positions and their due dates will be the same except due dates of jobs in two positions of \( j \) and \( k \) in both schedules. If \( d'_{[i]} \) represents the due date of the job in the sequence position \( i \) in schedule \( S' \), then \( d'_{[i]} = d_0[i] \) if \( i \neq j \) and \( i \neq k \), \( d'_{[j]} = d_0[k] \), and \( d'_{[k]} = d_0[j] \). The tardiness and earliness of the jobs in schedules \( S \) and \( S' \) will be defined as follows. \( T_{[i]} = \max(c_{[i]} - d_0[i],0) \), \( E_{[i]} = \max(c_{[i]} - d_0[i],0) \), \( T_{[j]} = \max(c_{[j]} - d_0[j],0) \), \( E_{[j]} = \max(c_{[j]} - d_0[j],0) \), \( E_{[k]} = \max(d_0[k] - c_{[k]},0) \), and \( E_{[k]} = \max(d_0[k] - c_{[k]},0) \). Since \( T_{[m]} = T'_{[m]} \), \( E_{[m]} = E'_{[m]} \) if \( m \neq j \) and \( \text{min} \) earliness and tardiness of jobs in the two positions \( j \) and \( k \) are considered. Considering that the positions of jobs in the two schedules are the same, the completion times will not be different and, according to the relations between the due dates of jobs, we will have

\[
T'_{[j]} = \max(c_{[j]} - d'_{[j]},0) = \max(c_{[j]} - d_0[i],0) < T_{[j]} = \max(c_{[j]} - d_0[j],0)
\]

\[
T'_{[k]} = \max(c_{[k]} - d'_{[k]},0) = \max(c_{[k]} - d_0[k],0) < T_{[k]} = \max(c_{[k]} - d_0[j],0)
\]

\[
E'_{[j]} = \max(d'_{[j]} - c_{[j]},0) = \max(d_0[j] - c_{[j]},0) < E_{[j]} = \max(d_0[j] - c_{[j]},0)
\]

\[
E'_{[k]} = \max(d'_{[k]} - c_{[k]},0) = \max(d_0[k] - c_{[k]},0) < E_{[k]} = \max(d_0[k] - c_{[k]},0)
\]

Therefore, Equations (8) to (11) will yield \( \max(T'_{[j]}, T'_{[k]}) \leq T_{[i]} \) and \( \max(E'_{[j]}, E'_{[k]}) \leq E_{[i]} \). We will also have \( \max(T'_{[j]}, T'_{[k]}) + \max(E'_{[j]}, E'_{[k]}) \leq \max(T_{[j]}, T_{[k]}) + \max(E_{[j]}, E_{[k]}) \). Consequently, it may be concluded that the sum of maximum earliness and tardiness in schedule \( S' \) is not larger than that of schedule \( S \).

#### 3.1.1. COMPLETION TIME BOUNDS

As we do not know the completion times of unscheduled jobs in the branch-and-bound algorithm, as required by lemma 1, we will use setup times to determine lower and upper bounds on the completion times of unscheduled jobs. These bounds are then used in a mathematical program whose optimal solution provides a lower bound for our problem \( |ST_{ad}|ET_{max} \).

To compute lower and upper bound for completion times of unscheduled jobs, first allowing \( pS_{PT_{[j]}}(\sigma') \) and \( pL_{PT_{[j]}}(\sigma') \) to equal the processing time of the job in position \( j \), respectively, if the jobs in \( \sigma' \) are sorted according to the shortest processing time, and longest processing time. If we pick the minimum amount of each job’s setup time, \( S_j = \min(S_{ij}) \) \( \forall i \), then \( S_{SST_{[ij]}}(\sigma') \) equals the selected setup time for the job in position \( j \), once the selected setup times are
sequenced according to the shortest setup time \( S_{SST[i]}(\sigma') \leq S_{SST[j]}(\sigma') \) if \( a < b \). If we pick the maximum amount of each job’s setup time, \( S_j = \max(S_i) \forall i \), then \( S_{LST[i]}(\sigma') \) equals the selected setup time for the job in position \( j \). Once the selected setup times are sequenced according to the longest setup time \( S_{LST[i]}(\sigma') \geq S_{LST[j]}(\sigma') \) if \( a < b \). So, \( LC[j] \) and \( UC[j] \) will be respectively the lower and upper bound of the completion time for the job in position \( j \).

\[
\begin{align*}
LC(j) &= \sum_{k=1}^{j} p_{LPT(k)} + s_{LST[j]} \quad (12) \\
UC(j) &= \sum_{k=1}^{j} p_{LPT(k)} + s_{LST[j]} \quad (13)
\end{align*}
\]

**Lemma 2.** \( LC[j] \) and \( UC[j] \) are respectively the lower and upper bound on the completion time of a job in position \( j \) of any sequence of unscheduled jobs.

**Proof.** Although the proposed lower and upper bound on completion times differs from that proposed by Schaller, in that we pick the minimum and maximum setup times of each job and also that there is no setup family for the jobs, the proof for our proposed lower and upper bound on completion times can be derived along the same lines as Schaller’s [19] since both have identical basic structures.

### 3.1.2. Lower Bound of \( l|ST_{sd}|ET_{max} \)

To find the lower bound for the problem of \( l|ST_{sd}|ET_{max} \), the following mathematical program is proposed.

**Program \( ET_{maxEDD} \).**

\[
\begin{align*}
\min & \quad z = \max_{j} (\max(c_{i,j} - d_{EEDD(j)}, 0)) + \max_{j} (\max(d_{EEDD(j)} - c_{i,j}, 0)) \\
\text{subject to} & \quad c_{i,j} \geq LC_{i,j} \quad (15) \\
& \quad c_{i,j} \leq UC_{i,j} \quad (16)
\end{align*}
\]

It should be noted that the decision variables in this program are the completion times of jobs in each position of a schedule. The objective value was shown above is the lower bound for the problem of \( l|\ ) ET_{max} \) and the completion times are restricted by their lower and upper bounds which were calculated using setup times.

In the problem \( l|ST_{sd}|ET_{max} \), let \( \delta' \) be the optimal sequence of jobs in \( \sigma' \) and \( C'_{i,j}(\delta') \) be the optimal completion time of the jobs in the positions of the sequence \( \delta' \). If we show that the optimal completion times of the jobs in \( l|ST_{sd}|ET_{max} \) are feasible for \( ET_{maxEDD} \), then the optimal value gained from \( ET_{maxEDD} \) will be a lower bound for the problem \( l|ST_{sd}|ET_{max} \).

**Lemma 3.** \( C'_{i,j}(\delta') \) in the problem \( l|ST_{sd}|ET_{max} \) are feasible for \( ET_{maxEDD} \).

**Proof.** According to lemma 2, for any sequence of unscheduled jobs (\( \delta \)), \( C_{i,j}(\delta) \geq LC_{i,j} \) and \( UC_{i,j}(\delta) \). Therefore, \( C_{i,j}(\delta') \geq LC_{i,j} \) and \( C_{i,j}(\delta') \leq UC_{i,j} \). The constraints imposed by \( ET_{maxEDD} \) also restrict completion times between \( LC_{i,j} \) and \( UC_{i,j} \). So, the optimal completion times of the jobs in \( l|ST_{sd}|ET_{max} \) will be feasible for \( ET_{maxEDD} \) and the optimal solution of \( ET_{maxEDD} \) will be the lower bound for \( l|ST_{sd}|ET_{max} \). ■

The program \( ET_{maxEDD} \) explores the completion times of jobs in the positions of a sequence independently. Therefore obviously the algorithm for obtaining the optimal solution of \( ET_{maxEDD} \) as follows:

**Step 0.** Set \( k = n \), \( C_{i}| = LC_{i} | j = 1, \ldots, n \). Enter step 1.

**Step 1.** If \( d_{EEDD[k]} \leq C_{k} \), go to step 3; otherwise, go to step 2.

**Step 2.** If \( d_{EEDD[k]} \leq UC_{k} \), let \( C_{k} = d_{EEDD[k]} \) and go to step 3; otherwise, \( C_{k} = UC_{k} \) and go to

**Step 3.** Set \( k = k - 1 \). If \( k > 1 \), go to step 2; otherwise, STOP.
3.2. DOMINANCE RULES

In this section, we present a dominance rule. Good dominance rules could lead to substantial improvements in algorithmic performance. Consider \( u \), as the last scheduled job in \( \sigma \), and \( \sigma' \) as a set of unscheduled jobs.

Assume that we obtain a modified processing time for the unscheduled jobs (\( \sigma' \)) by adding each job’s minimum setup time to its actual processing time. Then, using the modified processing times, these jobs will be sorted in the reverse MST order. If the maximum earliness of this sequence is less than the maximum earliness of the partial sequence \( \sigma \), this condition will be named **worst maximum earliness**.

**Lemma 4.** If the condition **worst maximum earliness** exists, there is an optimal sequence in which job \( i \in \sigma' \) will be scheduled in the first possible position of the schedule based on the following assumptions. See Fig (1).

\[
\begin{align*}
    s_{u,j} + s_{j} - d_{j} & \geq s_{u,j} + s_{i,j} - d_{j} \quad \forall j \in \sigma' \quad (17) \\
    s_{u,j} + s_{j} + \min_{k \neq i}(s_{k,j}) & \geq s_{u,i} + s_{i,j} + \max_{k \neq i}(s_{j,k}) \quad k \neq i, j \quad (18)
\end{align*}
\]

**Proof.** It can easily be shown that sum of maximum earliness and tardiness in schedule \( \sigma_0 \) is less than \( \sigma_1 \), by considering assumptions (17) and (18), therefore \( \sigma_1 \) is dominated.

3.3. UPPPER BOUND

We propose a heuristic algorithm that consists of two phases. In the first phase, an initial sequence is created based on a greedy procedure. Phase two, then, attempts to improve this initial sequence using two improvement procedures such as pairwise exchange of adjacent jobs and insertion algorithms.

3.3.1 CREATING AN INITIAL SEQUENCE

An initial sequence is created by a greedy algorithm. In greedy algorithm the set of candidate jobs consists of all those that are yet to be sequenced. The next job to be sequenced is selected using an appropriate greedy cost function. The cost function presented here considers slack time and will be different for tardy or early jobs. The construction steps are as follows. Assume \( S \) is the partial sequence and \( S' \) is the set of unscheduled jobs. Let \( u \) be the last scheduled job.

**Step 1.** Set \( S = \emptyset, S' = n, t = 0 \).

**Step 2.** Evaluate the slack time \( (d_{i} - p_{i} - S_{u,k} - t) \forall k \in S' \) of candidate jobs, jobs in set \( S' \).

**Step 3.** If the slack time is positive, which means an early job, we use function \( COST_{f} = \frac{((d_{k} - p_{k} - S_{u,k} - t))}{(p_{k} + S_{u,k})} \) for calculating the scheduling cost of the job. If the slack time is negative, which means a tardy job, we use function \( COST_{f} = \frac{((d_{k} - p_{k} - S_{u,k} - t))}{(p_{k} + S_{u,k})} \) for calculating the scheduling cost of the job. Then, select the job with the least amount of cost and put it in \( S \) at time \( t \) and update following parameters \( t = t + p_{k} + S_{u,k}, n \leftarrow n - 1, S' \leftarrow S' - \{k\} \).

**Step 4.** If \( n = 0 \), stop; otherwise, go to Step 2.

3.3.2. IMPROVEMENT PROCEDURES

The first procedure attempts to improve a sequence by exchanging the positions of two adjacent jobs. If the maximum earliness and tardiness of a sequence obtained by exchanging positions is less than that of the previous
sequence, then the exchange is retained; otherwise, the exchange is reversed. This procedure will be continued up to the last scheduled job. The second procedure tries to improve the sequence by inserting the job with the maximum tardiness in the first position of the sequence, then to the second, and the process continues until the job is placed in the position immediately preceding its original position. Then, the sequence with the least objective is retained. Then, the sequence obtained from the previous procedure is improved by inserting the job with maximum earliness from the last position in the sequence, then to the last but one, and the process continues until the job is placed in the position immediately following its original position. Then, the sequence with the least objective is retained. The proposed heuristic algorithm can be implemented in polynomial-bounded time.

4. Computational experiments

This section presents the results of the empirical experiments designed to evaluate the effectiveness of the proposed algorithm. The algorithm was implemented in Microsoft Visual C++ 6.0 and ran on a PC with a 3.4 GHz Pentium IV CPU and 512 M RAM. The proposed algorithm was evaluated using problem instances of various sizes and based on control parameters given in Table 1. Each problem set consists of 10 problems. The processing times of jobs were random integers from a uniform distribution over the range \([10,100]\) based on methods proposed in \([19, 20, 21]\). We will use a parameter for the setup proportion factor (SPF, the proportion of the range of setup times to processing time) which was originally due to Lou \([21]\). This factor decides the range of setup time distributions according to the range of processing time distributions. So setup times were created from \([10, spf \times P_{\text{max}}]\), where \(P_{\text{max}}\) is the maximum processing time of jobs. Generally, there are two control parameters to generate due dates for instances: due date range (\(R\)) and tardiness factor (\(\tau\)). Due dates for jobs were also randomly generated over the range \([\max(T(1-\tau-R/2),0),T(1-\tau+R/2)]\), where \(T = \left(\sum_j p_j + \text{average}(S)\right)\) \([20]\).

<table>
<thead>
<tr>
<th>size</th>
<th>(R)</th>
<th>(\tau)</th>
<th>SPF</th>
</tr>
</thead>
<tbody>
<tr>
<td>{8,10,12,15,20,25}</td>
<td>{0.2,0.4,0.6,0.8}</td>
<td>{0.2,0.4,0.6,0.8}</td>
<td>{0.2,0.6,1.1,1.4}</td>
</tr>
</tbody>
</table>

Sixteen different series of problems were generated by combining the two parameters \(R\) and \(\tau\). The total number of instances by parameter combinations will be 3840 (4×4×4×6×10).

4.1. Efficiency of the proposed algorithm

The measure of efficiency is the CPU time required to produce the solution. The maximum CPU time of each instance was set at 3600 seconds. The results of applying the B&B algorithm to all random instances show that all the problems with 8 to 15 jobs were optimally solved. The percentage of instances solved decreased with increasing job size. In fact, our algorithm was able to solve 93.56% of 20-job instances and 90.21% of 25-job instances. The average CPU time required for solving all instances in sizes 8,10,12,15,20,25 are respectively 0.02, 0.85, 43.64, 582.52, 1437.24, 1624.10. Increasing the problem size and setup time amounts increased CPU time, gradually reducing the number of optimally solved instances. Judging from the capability of the proposed branch-and-bound algorithm in optimally solving 97.5% of the instances with a size range of 8 to 25 jobs, it may be claimed that the proposed procedures in lower and upper bounds and dominance rule enjoys a high level of efficiency. Results in Table 2 present the average CPU time and also average percent of unexplored nodes caused by both lower bound and dominance rule in B&B tree for sixteen series of instances. By fathoming each node all its children in search tree will also be fathomed, calculating the number of the children on each node based on its level in the search tree regarded as an unexplored node. Of course the percent of unexplored nodes in different series shows the effectiveness of proposed lower bound and dominance rule.

In order to calculate the efficiency of the heuristic method, the average of relative deviation (ARD) from the optimum value is considered that calculated as follows:

\[
ARD = \frac{1}{n} \sum_{j=1}^{n} \frac{H_j - OPT_j}{OPT_j} \times 100
\]  

(19)

Where, \(H_j\) and \(OPT_j\) are objective function values of the heuristic and the branch-and-bound methods, respectively. The results in Table 3 actually show that the average percentage of deviation in the heuristic algorithm was less than 5% in all problem sets but the average deviation from the optimal solution was about 2.78%, which confirms its efficiency.

5. Conclusion

This paper addressed the single machine scheduling problem with sequence-dependent setup times to minimize the sum of maximum earliness and tardiness. A branch-and-bound algorithm was proposed including efficient lower and upper bounds and a dominance rule. The upper bound here consisted of two main phases. First, creating an initial sequence based on a greedy procedure including proper cost functions and, second, an improving process for the initial sequence obtained that includes pairwise and insertion procedures. The lower bound was derived by determining bounds on completion times of unscheduled jobs and solving a simple mathematical program. Evaluating the efficiency of the proposed algorithm shows that the proposed algorithm was capable of optimally
solving 8-job to 15-job instances with efficiency of 100% as well as 20-job and 25-job instances with efficiencies of 93.56% and 90.21%, respectively.

ABSTRACT

In the paper, we propose a new variable selection algorithm called Adjusted LARS, based on LARS(Least Angle Regression). Variable selection is mainly used to make prediction model. A main cause to prevent prediction model from having accuracy, is multi-collinearity. Original LARS calculates correlation between input variables and residual to decide the priority of input variables. The main idea of the Adjusted LARS is finding an orthogonal basis of input variables by QR factorization and calculating correlation between basis and residual. The Adjusted LARS is expected to exclude effect of multi-collinearity and improve rate of correctly-selected variables. Experiment results indicate improvement of the performance of the Adjusted LARS compared to the original LARS.

1. INTRODUCTION.

Variable Selection is one of the basic topics in data mining. It determines input variable that will be used in prediction modeling. Variable selection is used in mathematical application like supervised or unsupervised machine learning, regression, time series prediction, two-class or multi-class classification. And it is also used in text processing of internet documents, gene expression array analysis, and combinatorial chemistry [1].

Mathematical definition of variable selection is as follow. There is output vector \( Y \) and Set \( N \) of input vectors \( \{X_1, \cdots, X_p\} \) which are expected to having linear relation with \( Y \). And arbitrary subset \( S \) of \( N \) is set of selected input variable. \( S \) made a linear space and \( \bar{Y} \) is vector created by projecting \( Y \) on the linear space. And residual \( R \) is Euclidian distance and defined as. \( (1) \)

\[
R = \sum_{i \in S} (Y_i - \bar{Y})^2
\]

Definition of variable selection as using \( \bar{Y} \) and \( R \), it is finding \( S \) which make minimum \( R \) and minimum subset size simultaneously.

Variable selection is NP-hard problem [2]. LARS is one of many heuristic algorithm for variable selection. It has fast computational speed, and its accuracy is better than SRF(Stepwise Regression Forward) which is widely used algorithm [3]. The algorithm proposed in the paper base on LARS, and we develop it for more correct variable selection.

Main issues of variable selection are as follows. It must help understand how input variables effect on output, reduce measure data and data storage requirement, reduce training time and using time, improve accuracy of model. The paper focuses on reducing measure data and improving accuracy of model.

In session 2, we explain disturbing elements of Variable selection. And in session 3, we review existing research such as stepwise regression and LARS. In section 4 we explain more details of these issues and offers solutions to resolve the problem. In session 5, we perform simulations and analyze the results, to verify the algorithm SRF, LARS, and to compare the algorithm proposed in the paper.

* Corresponding author: Tel.: (82) 2-3290-3396; Fax: (82) 2-929-5888; E-mail: jungeol@korea.ac.kr
2. ELEMENT OF THE INTERFERENCE

In variable selection there are two main causes which prevent prediction accuracy of algorithm. The one is over-fitting, the other is multi-collinearity.

If some algorithm chooses specialized variables for sampling data we call that variable selection is over-fitted. When we make some model, we use sampling data and we choice the model with some input variable that fit for sample data. But there is no guarantee that selected variables fit for population. Over-fitting occurs when statistical model has too many parameters. Especially, if sampling data is biased or includes singular value, statistical model differ with real model because of over-fitting. [3]

Multi-collinearity is divided into exact multi-collinearity and near multi-collinearity. Exact multi-collinearity means that input variable \( X \) is linearly dependent on some other input variable. Near multi-collinearity means that input variable \( X \) is not expressed by other input variable' linear combination, but expressed as follow (1) \( C \) is arbitrary vector which is not null-vector. [4]

\[
XC = \begin{bmatrix} x_{11} & \cdots & x_{1p} \\ \vdots & \ddots & \vdots \\ x_{n1} & \cdots & x_{np} \end{bmatrix} \begin{bmatrix} c_1 \\ \vdots \\ c_p \end{bmatrix} \approx 0
\]

(1)

Exact multi-collinearity is not an important problem in variable selection. Because it can be detected and removed easily by LU decomposition and singular value decomposition. But near multi-collinearity is not solved exactly. If input variables with near multi-collinearity exist in set of selected variable, the prediction model which consisted of that set is unstable [3]. And if we exclude input variables with near multi-collinearity collectively, we can exclude important variables that effect on output in combination with each other [1].

3. REVIEW EXISTING RESEARCH

Various heuristic algorithms for variable selection have been researched. Sometimes their prediction accuracy is prevented by over-fitting problem and near multi-collinearity. We handle improvement in that problems. Efromyon proposed stepwise regression which is widely-used heuristic algorithm [5]. LARS improves prediction accuracy of stepwise regression. The paper considers over-fitting and multi-collinearity to adjust LARS. SRF use forward selection process and greedy rule which stand on the basis of correlation between input vector and residual. We can see the disadvantage of SRF in counter example of existing research. SRF exclude non-selected input variable correlated with selected input variable. So it can't consider various subset of the input variable [3].

Improved algorithms for this disadvantage of Stepwise Regression are Stagewise, Lasso [6], LARS (Least Angle Regression, the "S" suggesting “Lasso” and “Stagewise”) and so on. Stagewise and Lasso can be transformed into LARS, this transformation proved mathematically. That means these algorithms have same prediction accuracy. And calculative performance of LARS is better than that of Stagewise and Lasso [5]. Therefore, we focus on the LARS. LARS uses correlation between correlation between input vector and residual. This measure equals to that of Stepwise regression. But LARS improves prediction accuracy, using different direction select and step length. So LARS effects on counter example of SRF [3].

However, LARS has some fatal disadvantage. [5] shows disadvantages. Discussion of Robert A. Stine shows that if there is multi-collinearity between input variables, LARS is exposed to serious over-fitting problem. In real situation, this problem effects on fault variable selection. In generally, we use as many candidate input variables as possible to improve accuracy of model. Increasing number of candidate input variables bring about high chance to multi-collinearity. In this case LARS has high chance to making unstable prediction model.

We judge that one of the causes which make the problem described in the preceding paragraph is under-estimation of correlated input variables. More precisely, as iterations progress and some input variables are selected, part of the explanation made of selected variables is removed from residual vector which is measure of selecting candidate variables. Then the selected variables and care for other variables that have a high rating is relatively lower. And we improve the problem in that point of view.
4. MAIN IDEA

The problem which is improved in the paper exist both 'SRF' and LARS. And explain improvement of SRF is easier to understand visually. So I will explain the problem of the SRF and improving method.

We assume that three candidate input variables is considered to create prediction model for one output variable y. Process for selecting variables used in SRF is described in Figure 1.

![Figure 1: Process of SRF](image)

In figure 1, each input variable vectors and output variable vector are expressed with ellipses of same size. Overlap of two ellipses is the vector projected on another vector. In addition, divide the overlap area by ellipse area is absolute value of correlation between two vectors. In this point, proposed algorithm is as described below. Figure of step 1 describe comparison between each of correlations between output variable and input variables. In Figure 1 overlap area between \( X_1 \) and \( y \) is largest. So \( X_1 \) is selected and constitute \( S \). In step 2 and step 3, characteristic of algorithm is well brought out. In step 2 \( y' \) is projection vector \( y \) on \( X_2 \). Next we calculate absolute value of correlations between \( y' \) and input variable left (\( X_1, X_3 \)). In this step, the variable which has much overlap area with \( X_2 \), is underestimated. As a result, we can't select correct variable and accuracy of prediction model will be low.

These problems can be solved in the same way as the Figure 2. When we calculate correlations, use translated vectors \( X_1' \) and \( X_3' \) instead of original vector \( X_1 \) and \( X_3 \). \( X_1' \) is projection vector \( X_1 \) on \( X_2 \). \( X_3' \) is made in same way. In this way, we can calculate more accurate measure using correlation.

![Figure 2: Process of proposed algorithm](image)

We modify a pseudocode of SRF as described below.

**Pseudocode of Stepwise Regression Forward**

- **Initialization**
  A. Initialize residual vector as output vector \( Y \)
  B. Initialize \( S, N \) (set of input vector) as described below
    \[
    S = \{ \}, \quad N = \{ i \mid i \text{ is index of input variable } X_i \} \]
  C. Set \( F \) to \( \text{Enter} \) value which is a selection criterion
  D. Calculate initial residual value as below. \( n \) is number of data, \( p \) is iteration number.

\[
R_p = \sum_{i=1}^{n} Y_i^2
\]  

(3)
• **Step 1**
  A. Calculate correlations between $X_i$ and residual vector. $X_i$ is an element of $N$.

  \[
  Corr(X_i, \text{Residual}) = \frac{\sigma_{X_i, \text{Residual}}}{\sigma_{X_i}, \sigma_{\text{Residual}}}
  \]  
  (4)

  B. Find $X_{\text{max}}$ which have maximum absolute correlation.

• **Step 2**
  A. Set residual vector as (5).

  \[
  \text{Residual} = \text{Residual}_{\text{old}} - \frac{\text{Residual}_{\text{old}}^T X_{\text{max}}}{X_{\text{max}}^T X_{\text{max}}} X_{\text{max}}
  \]  
  (5)

  B. Calculate residual value as (6).

  \[
  R_{p+1} = \sum_{i=1}^{n} \text{Residual}_i^2
  \]  
  (6)

• **Step 3**
  Calculate $F - \text{Statistics}$ as (7). Where $k$ = number of selected variable, $|S|$

  \[
  F - \text{Statistics} = \frac{R_p - R_{p+1}}{R_{p+1}} (n - k - 2).
  \]  
  (7)

  If $F - \text{Statistics}$ is lower than $F - \text{to} - \text{Enter}$
  A. Set $S$, $N$ as (8).

  \[
  S^+ = X_{\text{max}}, \quad N^- = X_{\text{max}}
  \]  
  (8)

  B. $R_p = R_{p+1} + 1$

  C. Go to Step 1

  If $F - \text{Statistics}$ is higher than $F - \text{to} - \text{Enter}$, complete algorithm.

A pseudocode of the new algorithm, the modifications to the code as described above. In step 1, change (a) as below.

  A. Calculate correlations between $X_{i'}$ and residual vector. $X_{i'}$ is an element of $N$. In first iteration, $X_{i'}$ equal to $X_i$.

  \[
  Corr(X_{i'}, \text{Residual}) = \frac{\sigma_{X_{i'}, \text{Residual}}}{\sigma_{X_{i'}}, \sigma_{\text{Residual}}}
  \]  
  (9)

And in step 3, add below process after B.

  C. $X_{i'} = X_i - \frac{X_i^T X_{\text{max}}}{X_{\text{max}}^T X_{\text{max}}} X_{\text{max}}, \quad i \in N$

  (10)

Calculation direction method of LARS same as that of SRF. In other words, calculate correlations between residual vector and input vectors. In this time, LARS only make orthogonal selected input vector on residual vector but do not on non-selected input vector. And select input variable whose correlation is largest. So the same problem described above, occur in LARS. The non-selected vector which highly related with output variable and selected input vectors will be underestimated in calculating correlation. As a result, it may not be the correct choice of variables.

To adjust this problem add the formula (10) to pseudocode LARS, and after then use $X'$ instead of $X$. This modified algorithm will call Adjusted LARS. Pseudocode of Adjusted LARS is described follow.
Pseudocode of the Adjusted LARS

- **Initialization**
  A. Normalize input vector $X_i$ (for $i = 1, \cdots, p$), output vector $Y$ by mean and variance
  B. Initialize $S_N$ (set of input vector) as described below
    
    $$ \mathcal{S} = \{\}, \quad \mathcal{N} = \{i \mid i \text{ is index of input variable } X_i\} $$
  C. Initialize residual vector as output vector $Y$
  D. Initialize sign variable $S_i$ (for $i = 1, \cdots, p$) as 0. $S_i \in \{-1, 0, 1\}$

- **Step 1**
  A. Calculate correlations between $X_i'$ and residual vector (9). $X_i$ is an element of $N$. In first iteration, $X_i'$ equal to $X_i$.
  B. Select input variable $\text{Corr}_{\max}$ which has maximum correlation.
    
    $$ \text{Corr}_{\max} = \max_{i=1}^n (\text{Corr}_i) $$
  C. Save sign of correlation between $X_i'$ and residual vector in $S_i$.
  D. Set $S_N$ as (8).
  E. Define vector $\mathbf{X_s}$ as (12)
    
    $$ \mathbf{X_s} = (\cdots, s_0, x_0, \cdots)_{i \in S}, s_i = \pm 1 $$

- **Step 2**
  A. Set residual vector as (13).
    
    $$ \text{Residual} = \text{Residual}_{old} - \frac{\text{Residual}_{old}^{T} \mathbf{X'}_\max \mathbf{X'}_\max}{\mathbf{X'}_\max^{T} \mathbf{X'}_\max} \mathbf{X'}_\max $$
  B. Calculate residual value as (6).
  C. Calculate as follow.
    
    $$ A_S = [I_S^{T} (X'_{S}^{T} X'_{S})^{-1} 1_S]^{-\frac{1}{2}} $$
    
    $$ W_S = A_S (X_{S}^{T} X'_{S})^{-1} 1_S $$
    
    $$ u_S = X_S W_S $$
    
    $$ a_N = X_N^{T} u_S $$
    
    1s is vector whose all elements are 1 and size is $p$. And where $j \in N$
    
    $$ \gamma^+_j = \frac{\text{Corr}_{\max} - \text{Corr}_j}{A_S - a_{N_j}}, \gamma^-_j = \frac{\text{Corr}_{\max} + \text{Corr}_j}{A_S + a_{N_j}} $$
    
    $$ \gamma_j = \max(\gamma^+_j, \gamma^-_j), \ \gamma = \min(\gamma_j) $$
    
    $$ X_{\max} = X_j, \ \min(\gamma_j) = \gamma_j $$
    
    If $\gamma > 0$, $s_i = +1$ else $s_i = -1$
    
    $$ \text{Residual} = \text{Residual} - \gamma A_j, \ \text{Corr}_j = \text{Corr}_j - \gamma A_j, \ j \in N $$

- **Step 3**
  Repeat Step1, Step2 until satisfy stopping criterion (defined by user)

The Adjusted LARS different from LARS in searching direction. In figure3 comparing Adjusted LARS with LARS, the Adjusted LARS use $X_{\cdot}'$ (from Formula 10) instead of $X_{\cdot}$. If we use it, the point of same correlation is pulled if $X_{\cdot}$ and $X_{\cdot}'$ is not orthogonal. Because underestimation of $X_{\cdot}'$ which is generated by correlation between $X_{\cdot}$ and $X_{\cdot}'$, is reduced.
5. EXPERIMENT

To compare new algorithm with LARS, we make an experiment with simulation data. The data is generated by the rules described in [7]. It generates two classes of data. We set the correlation (between input variables) of the one class to 0, and correlation of the other to 0.9.

We generate data as follow. The number of rows (the number of candidate input variables) \( m \) is 400. And the number of column (the number of data) \( n \) is 800. Input variable \( x_i \) is generated by multivariate normal distribution and satisfies i.i.d. \( N(0,1) \). Covariates of \( x_i \), for \( i = 1, \cdots, n \), were generated independently from a multivariate normal distribution with zero mean and with covariance satisfying \( E(x_i, x_j) = \rho^{ij} \). Experiment independently \( \rho \) is 0 or 0.9. And white noise is normally distributed whose mean is 0, standard deviation is 1. \( \beta_j \) coefficients were in 15 clusters of 7 adjacent variables centered at every 25th variable. The value is calculated (14).

\[
\beta_{25a+j} = | h - j |^{25} | j < h, h = 4_i (\alpha = 1, 2, \cdots, 15) 
\]

As a result, we generate 105 variables whose \( \beta \) is not 0, and generate 295 variables whose \( \beta \) is 0. After then, to adjust theoretical \( R^2 \) value to 0.75, \( \beta_j \) took additional compensation by multiplying the specific value [7]. Although the number of variables whose \( \beta \) is not 0 is changed, this type of simulation has the advantage by considering different configurations for the dimension \( m \), sample size \( n \), correlation \( \rho \) and the number of nonzero coefficients [8]. For each \( \rho \) correlation setting simulations were repeated 100 times independently. Results are recorded in Table1.

<table>
<thead>
<tr>
<th>( \rho = 0 ) (uncorrelated X)</th>
<th>( \rho = 0.9 ) (correlated X)</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \rho \text{ pe}(\mu) )</td>
<td>( \rho \text{ pe}(\mu) )</td>
</tr>
<tr>
<td>--------------------------------</td>
<td>--------------------------------</td>

<td>LARS 210.69 0.907 126.63 0.547 0.055 99.51 0.962 75.77 0.347 0.135</td>
<td></td>
</tr>
<tr>
<td>Adj-LARS 215.70 0.911 60.77 0.321 0.000 130.31 0.966 62.34 0.324 0.000</td>
<td></td>
</tr>
</tbody>
</table>

We must select variables whose \( \beta_j \) is not 0 (true variable) and must not select variables whose \( \beta_j \) is 0 (false variable). TotalMiss is the total number of misclassified variables. FDR is the false discovery rate which is the rate false variable is selected. FNR is the false nondiscovery rates defined as the rate true value is not selected. To represent
TotalMiss, FDR, FNR values we use the averaged values from the 100 simulations. The 'M' recorded in the table is the average number of variables selected by a procedure. The performance value (prediction power) \( pe(\hat{y}) \) (15), again averaged over the 100 simulations [8].

\[
pe(\hat{y}) = 1 - \frac{\| \hat{y} - y \|^2}{\| y \|^2}
\]

(15)

In this experiment each three algorithm use \( C_p \) criterion. \( C_p \) can be calculated as (16).

\[
C_p(\hat{y}_k) = \frac{\| y - \hat{y}_k \|^2}{\sigma^2} - n + 2k
\]

(16)

The overall conclusion from [Table 1] is follow.

- In Adjusted LARS, Total-Miss, FDR, FNR is lower than SRF and LARS. It means that fault variable selection is reduced. Especially in both case, FNR is 0. In this experiment, the Adjusted LARS doesn't miss meaning variable.

- In correlated case, \( m \) of LARS is small than Adjusted LARS. And FDR of LARS is similar to Adjusted LARS'. But FNR of LARS is higher than Adjusted LARS'. And in uncorrelated case FDR is high. It means that LARS throws correlated input variables rapidly and Adjusted LARS makes decisions more carefully.

- A performance of the Adjusted LARS is better than other two algorithms.

6. Conclusion

We presented the Adjusted LARS algorithm to improve accuracy of prediction model. We consider multi-collinearity between input variables, and to improve algorithm we remove correlated factor between input variables by creating orthogonal vector. To make orthogonal vector we use QR factorization in algorithm [9].

In the experiment, we can see the results were better than the original LARS algorithm. The number of misclassified variables is decreased. Especially, the number of throwing meaning variable is reduced a lot. But we must to prove that the results of experiment with different open data and real process data. And verification selection criteria for further research should be. For example AIC (Akaike information criterion), BIC (Bayesian Information Criterion), \( C_p \) can be used. And to improve algorithm more correct, we must consider over-fitting problem. One of the method to avoid over-fitting is n-fold cross-validation. To apply n-fold cross-validation we must to define rule to select variables which are selected in each fold.

A Tabu Search approach for pallet transport management problem

Pierpaolo Caricato*, Antonio Grieco, and Francesco Nucci

Department of Innovation Engineering
University of Salento
Lecce, 73100, Italy

ABSTRACT

In Flexible Manufacturing System, parts move among the resources in order to be processed. Usually, a classical pallet transport system adopts the railway carrier approach. Consequently, the transport layout is linear and bidirectional. Each time a pallet/part has to be moved in the system, a transport trip is issued and waits to be satisfied by the transport system. The pallet transport management decides the sequence the transport trips have to be executed. In general, the objective consists in minimizing the makespan to perform all the trips. When high rate values of the parameter “number of transport trips per time unit” are required, the transport system can become the system bottleneck. This leads to starvation and blocking on machining resources due to parts waiting to be moved by transport system. In such a case, the problem is multi-objective. The main objective consists in the minimization of the idle resource time due to transport system; whereas the minimization of the transport makespan is secondary. The solution consists in determining the exact list of pallet trips performed by the transport system. The considered approach proposes a Tabu Search based approach to solve the illustrated problem. In particular, in order to solve efficiently the problem, we considered the list of trips to be performed by the vehicle as a solution. The validation of the method is performed on a case study in order to compare the performance with state-of-the-art approaches.

1. INTRODUCTION

Recently, new ideas related with the design of manufacturing system architectures provided with the correct level of flexibility in order to face the specific production problem has been introduced. Such approaches tune system flexibility on the production problem, in order to cope with the uncertainty related to product evolution [1]. This problem leads to develop a methodology to analyze the requirements in terms of flexibility of the firm, and to design the system starting from the flexibility levels required. Consequently, new manufacturing systems, with the minimum level of flexibility required, have to be designed. Considering a classical Flexible Machining System (FMS), if the system flexibility is reduced, some CNC machines can be replace by dedicated machines not able to perform the entire part program. Consequently, parts need processing operations on different machines. As a result, a relevant management question consists in configuring the transport system in order to face the higher rate of pallet transfers. In FMS, a classical transport solution consists in a vehicle carrier. If the pallet transfer rate increases, the management policy has to avoid the transport system becomes the system bottleneck. Indeed, if pallet trip is not performed in time, a machine gets idle. Such a problem is common in other fields (sewing, assembling) in which resources are placed in a linear layout and a vehicle is adopted as transport system.

Managing a transport system efficiently is an important task [2]. In [3] a review on design and control of automated guided vehicle systems is presented. Various key related issues are addressed including guide-path design, determining vehicle requirements, vehicle scheduling, idle-vehicle positioning, battery management, vehicle routing and deadlock resolution. In [4], Kim and Tanchoco propose an algorithm based on Dijkstra’s shortest-path method to schedule vehicles based on the nodes’ time windows. This approach produces a deadlock-free schedule. However, as noted by the authors, a small change in the schedule may destroy it completely. Taghaboni and Tanchoco, see [5], introduce an incremental route planning and scheduling algorithm. Other approaches are introduced in [6] and [7]. More details about the vehicle routing issue can be found in [8].

On one hand, the Vehicle Routing Problem (VRP) has been widely investigated, in order to design least cost routes from one depot to a set of geographically scattered points. On the other, the scheduling of vehicle tasks received less attention and has always been classified as a special case of VRP [9].

The problem considered in this work deals with the management of the transport system associated with a job shop production plant. Such a plant requires pallets to be moved by a vehicle along a railway system passing through inline disposed machines. Parts are processed by machines in accordance to a given part program and are transferred from a machine to the following one. Each part request to be transferred from a station to another along the line is referred as Part Trip (PT). Transport system manager has to schedule the PT in order to allow the best use of the transport vehicles in the system. This lead to: minimizing empty travel performed by the vehicle between two consecutive PTs. The optimal use of the transport system allows reducing machine idle time (due to lack of parts).

The remainder of the paper is organized as follows. In the next section, we describe the problem statement and its mathematical formulation. Then, we formulate the proposed approach adopting Tabu Search technique. In the last section, we report the experimental campaign and the corresponding results we obtained to validate our approach.

2. PROBLEM STATEMENT

The problem treated considers a set of tasks (or trips) characterized by an origin, a destination and a duration. The tasks are given a priori and are composed of one or several activities. Between two successive tasks there is an inter-task transit time period of a certain duration and cost. The problem to be solved consists of forming a schedule, i.e., sequences of tasks where each task is performed exactly once. This type of problem is encountered in several fields, such as airline, rail, schoolbus and urban transportation. Dantzig and Fulkerson [10] were the first to formulate a fixed schedule problem as a minimum cost flow circulation problem.

An example of system layout is reported in Figure 1. The resources are placed in line along the path of the vehicle according to an assigned distance. The speed vehicle is assumed to be constant.

![Figure 1: System layout](image)

The Vehicle Scheduling Problem with Time Windows and a unique vehicle (VSPTW) can be formulated as Traveling Salesman Problem with Time Window (TSPTW) considering the trips to be performed as nodes of a graph. Consider a set of \( n \) trips \( \{ T_1, T_2, ..., T_n \} \), where trip \( T_i \) has a given duration \( \lambda_i \) and \( \delta_i \) is the due date in which \( T_i \) has to be completed. Consider also an initial position in which the vehicle is stationed. Let the set of nodes \( N = \{1, 2, ..., n\} \) represent the set of trips, and node \( \{n + 1\} \) represent the single depot. Let also \( t_{ij} \) denote the travel time between the ending point of trip \( T_i \) and the starting point of trip \( T_j \). Note that in general \( t_{ij} \neq t_{ji} \). For simplicity, we will assume that \( t_{ij} \) includes the duration \( \lambda_i \) of the trip \( T_i \).

Let \( c_{ij}, i,j \in N \) be the cost incurred if a vehicle performs trip \( T_j \) immediately after trip \( T_i \). This cost is usually a function of the distance between the ending point of trip \( T_i \) and the starting point of trip \( T_j \). It can also include the fixed cost incurred to cover one of the trips, say trip \( T_i \). Let next \( c_{n+1,j} \) be the cost incurred if the vehicle undertakes trip \( T_j \) as the first trip after leaving the depot. Similarly, the cost \( c_{j,n+1} \) is incurred when trip \( T_j \) is the last trip before the vehicle returns to the depot. This cost can also include the fixed cost incurred to cover trip \( T_j \). The problem consists of finding an assignment of vehicles to trips in such a way that:
A Tabu search approach for pallet transport management problem

- each trip is covered exactly once by a vehicle;
- vehicle leaves from the depot, covers a sequence of pairwise compatible trips and returns to the depot at the end of the route;
- the sum of the costs of the routes traveled by the vehicles used in the solution is minimized;
- each trip has to be completed before a given due date.

By making duplicates of the depot node, \( o \) and \( d \) for the origin and the destination of any feasible route, it is simple to describe the path origin and destination. This allows checking if the due date constraints are enforced. To formally describe the problem, define the graph \( G = (V, A) \), where \( V = N \cup \{o,d\} \) is the set of nodes and \( A \) is the set of arcs as described in (1). Consequently, the number of arcs is equal to (2).

\[
A = \{(o,j) | j \in N\} \cup \{(i,j) | i,j \in N, i \neq j\} \cup \{(i,d) | i \in N\}
\]

(1)

\[
|A| = n + n(n - 1) + n = 2n + n^2 - n = n^2 + n = n(n + 1)
\]

(2)

Let the variables \( x_{ij} \) be the binary flow on arc \((i,j) \in A\): \( x_{ij} = 1 \), if a vehicle covers trips \( T_j \) after trip \( T_i \), and \( x_{ij} = 0 \), otherwise. Moreover, the variables \( \tau_i \) specifies the start of service at node \( i \), \( i \in N \cup \{o,d\} \).

\[2.1. \text{Formulation} \]

The model can be formulated as a pure network flow problem:

Minimize

\[
\sum_{(i,j) \in A} c_{ij}x_{ij}
\]

subject to:

\[
\sum_{j \in N \cup \{d\}} x_{ij} = 1 \quad \forall i \in N
\]

(4)

\[
\sum_{j \in N} x_{oj} = 1
\]

(5)

\[
\sum_{i \in N \cup \{o\}} x_{ij} - \sum_{i \in N \cup \{d\}} x_{ji} = 0 \quad \forall j \in N
\]

(6)

\[
\sum_{i \in N} x_{id} = 1
\]

(7)

\[
x_{ij}(\tau_i - t_i - \tau_j) \leq 0 \quad \forall (i,j) \in A
\]

(8)

\[
\tau_i + \lambda_i \leq \delta_i \quad \forall i \in N
\]

(9)

\[
x_{ij} \in \{0,1\} \quad \forall (i,j) \in A
\]

(10)

\[
\tau_i \geq 0 \quad \forall i \in N \cup \{o,d\}
\]

(11)
It is a nonlinear program with $O((n + 2)^2)$ variables and $O((n + 2)^2)$ constraints.

The objective function (3) seeks to minimize the sum of travel. Constraints (4) ensure that each trip is performed exactly once, while constraints (5)-(7) are flow conservation constraints. Constraints (8)-(9) ensure feasibility of the time schedule. Note that the sub-problem defined by (4)-(7) and (10) is a minimum cost flow problem (in fact an assignment problem with $(n + 2)$ rows and $(n + 2)$ columns). Whereas, the additional constraints (8), (9) and (11) deal with the time schedule. It is important to note that sub-tours are eliminated by constraints (8). Using a big $M$ constant, such constraints (8) can be linearized and rewritten as (12).

\[ t_i + t_{ij} - t_j \leq M(1-x_{ij}) \quad \forall (i,j) \in A \]  

(12)

Note that the large constant $M$ can be replaced by $M_{ij} = \delta_i + t_{ij}, (i, j) \in A$. In this way, it is possible to use (13) instead of (8).

\[ t_i + t_{ij} - t_j \leq (\delta_i + t_{ij})(1-x_{ij}) \quad \forall (i,j) \in A \]  

(13)

Research on the TSPTW has been scant. In [9] and [11], it is proved that such a problem is NP-hard. Anyway, considering the linear layout case, researches have investigated the vehicle routing problems on a line-shaped network [12]. The solution methods for the VRPTW have been studied in [13] and [14]. In particular the most interesting approaches that are suitable to be applied in our case are in the following.

Homberger and Gehring [15] present two evolution strategies, together with GAs and evolutionary programming, the evolution strategies form the class of evolutionary algorithms. By definition, the main differences between these three types of algorithms lie in the representation and in the role of mutation. In Evolution Strategies (ES) of [15] the individual representation includes a vector of so-called “strategy parameters” in addition to the solution vector and both components are evolved by means of recombination and mutation operators these strategy parameters refer to how often a randomly selected local search operator is applied. Bent and Van Hentenryck [16] present a Two Stage Hybrid Metaheuristic (TSHM), where in the first stage a basic simulated annealing is used to minimize the number of routes, and the second stage focuses on distance minimization using the Large Neighborhood Search. Gambardella et al. [17] use an Ant Colony Optimization (ACO) approach that minimizes the total traveled distance.

3. Tabu Search Approach

Tabu search (TS) is a local search procedure that iteratively moves from a current solution to its best neighbor even if this causes deterioration in the objective function value [18] in order to avoid being locked into local minimums. To avoid cycling, a short term memory (like a tabu list or tabu attributes) is used. In addition, a diversification can be used to visit new regions of the solution space, whereas intensification is used to explore the neighborhood of the current solution.

The permutation of the trips to be accomplished has to be determined in order to optimize the system’s performances. Given a certain permutation, this can be adopted as the current solution for the TS algorithm. In particular, a generic solution for the TS algorithm is represented by a permutation of the indexes in the afore-defined set $N$.

3.1. Initial Solution

TS needs a feasible initial solution in order to start exploring the solution space. This first solution is determined through a greedy constructive algorithm. At each stage, the algorithm selects the unselected trip nearest to the current trip. We choose among the trips to be performed, the one having the starting point that is nearer to the initial position of the vehicle. The next trip to be performed is selected, among the remaining trips, considering the minimal cost required to move from the arrival station of the currently selected trip to the departure station of the candidate trip. Using the notation introduced before, this can be formalized as:

List $M = \emptyset$
prec $= o$

for (j=1 to n)
A Tabu search approach for pallet transport management problem

\[ m_j = \arg \min_{i \in N \cdot M} \{c_{\text{prec},i}\} \]
\[ M.\text{add}(m_j) \]
\[ \text{prec} = m_j \]

where \( M = (m_1, m_2, ..., m_n) \) is the initial solution for the TS: \( m_1 \) is the first trip to be performed, \( m_2 \) the second one and so on.

3.2. MOVE AND NEIGHBORHOOD

Once an initial solution has been determined, the following solutions to be explored are determined through moves, i.e. defining a way to determine a new feasible solution from the current one. In the proposed approach a generic move is determined using a 2-opt approach [19]. Hence, the neighborhood of the current solution is given by the set of all possible swaps that can be made. The size of the neighborhood is hence given by (14).

\[ \binom{n}{2} = \frac{n \cdot (n - 1)}{2} \]  \hspace{1cm} (14)

Each solution in the neighborhood has to be tested for feasibility. With the proposed move, indeed, it is not possible to guarantee the feasibility of the new solution, since the respect of the due date constraint is not necessarily satisfied. A measure \( \Phi \) of the infeasibility of a given solution can be defined, using (9), as reported in (15).

\[ \Phi = \max_i \{0, \tau_i + \lambda_i - \delta_i\} \]  \hspace{1cm} (15)

The evaluation of the moves in the neighborhood is determined calculating the delta-cost between the current solution and the new solution defined by the selected swap. Let \( i \) in \( N \) be a generic trip: we define the before(\( i \)) and after(\( i \)) functions that indicate in the current solution, respectively, the trips to be performed before and after \( i \). Let \( i \) and \( j \) in \( N \) be the trips to be swapped, the delta-cost is equal to (16).

\[ \Delta = [c_{\text{before}(i), j} + c_{\text{after}(j), i} + c_{\text{before}(j), i} + c_{\text{after}(j), i}] - [c_{\text{before}(i), i} + c_{\text{after}(i), i} + c_{\text{before}(j), j} + c_{\text{after}(j), j}] \]  \hspace{1cm} (16)

where the former term is the contribution of the trips involved in the swap to the overall cost function in the new solution, while the latter is the same contribution in the current. The 2-opt approach is described in Figure 2.

\[ \begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{move_2opt.png}
\caption{Move with 2-opt approach and delta-cost calculus}
\end{figure} \]

Once all moves have been performed, only one has to be chosen. If at least one of the candidate new solutions are feasible, then the selected solution is the one having the minimum \( \Delta \). On the contrary, if all candidate solutions are infeasible, then the one having the minimum \( \Phi \) is selected.

3.3. TABU LIST AND DIVERSIFICATION

In order to avoid local minimums, TS uses a tabu list that temporarily forbids certain moves. In the considered approach, each move is characterized by two important attributes: namely, the two trips involved in the selected swap. Both indices of the applied swap are stored in the tabu list; hence none of them can be selected for a swap for a given number of iterations.

Diversification is used in order to escape from local minimums in the cases in which the tabu list approach is not sufficient. A maximum number of iterations without improvement in the objective function is determined. When this occurs, the solution is changed using a diversification approach. In the proposed algorithm, we diversify using a 3-
opt approach [12]. We consider every possible sequence of three adjacent trips (hence \( n-2 \) triplets) in the current solution and we generate the two candidate solutions that are given by the permutations of the three selected trips. We then select the best (or the least unfeasible) solution among the generated ones, see Figure 3.

![Figure 3: Diversification with 3-opt approach.](image)

4. CASE STUDY

4.1. EXPERIMENTAL CAMPAIGN

The mechanism for the generation of case studies has been developed and tuned on the basis of an experimental campaign performed on industrial case studies, having the linear layout transport system. In particular, we observed cases in which the necessity the high transport rate leads to resource idle times. The case studies have been generated considering three different parameters:

1. Number of trips to be scheduled (\( n \))
2. Number of stations in the linear path
3. Due date looseness

The number of task to be scheduled directly influences the problem complexity. Since, the higher is the number of stations, the higher is the number of trip requests, also the second parameter affects the complexity. The third parameter describes the cardinality of the feasible solutions. If due date looseness is high, several feasible solutions exists and it is possible to find the optimal one minimizing the overall cost. Otherwise, critical trips force the solution algorithm to schedule them early to avoid lateness.

Due dates have to be carefully generated in order to avoid empty domain sets. The generation algorithm for trip due dates we adopted is the following:

1. Define a looseness parameter \( \alpha \) between 0 and 1
2. Calculate \( D_1 \) as the average of trip durations
3. Calculate \( D_2 \) as the average of travel time between two trips
4. Calculate the estimate of the total trip duration as \( (D_1 + D_2) \cdot n \)
5. Set the due date \( d_i = (D_1 + D_2) \cdot (1 + \alpha) \cdot \rho_i \) where \( \rho_i \) is a random number between 0 and 1 (uniform distribution).

This method calculates an estimation of the total duration trip considering the average values of the transition times and trip length times. The estimation is increased by a looseness factor \( \alpha \) (e.g. 20%). Due dates are randomly generated between 0 and the estimation. This method well approximates the distribution of real due date data in which low due date values lead to high priority trips.

The considered test case have been generated by considering the combination between the number of trips \( n \) in the set \{20, 40, 60, 80, 100\} and the due date looseness \( \alpha \) in the set \{0, 0.25, 0.5, 0.75, 1\}. The number of stations is
set to n/2+2. The initial vehicle position is set to the middle station of the linear path. For each experiment, a time limit of n/10 minutes has been established. The proposed Tabu Search (TS) approach has been compared with the three methods presented at the end of section 2: Evolution Strategies (ES) [15], Two Stage Hybrid Metaheuristic (TSHM) [16] and Ant Colony Optimization (ACO) [17].

### 4.2. Computational Results

The experimental campaign has been performed on a PC Intel Core 2 CPU 2.33 GHz 1GB RAM with Microsoft Windows XP Pro SP3. Results are reported in Table 1. In columns 4-7, the objective value of the best solution found, using one of the methods, is reported. In the last three columns the gap (%) between the TS solution and one of the three benchmarks is reported. If the gap is positive, the TS solution is better than the other one.

For each experiment, at least a feasible solution exists. In the first five experiments, all the methods are able to find the same optimal solution. In such cases (exp. 1-5) we were also able to solve the MIP problems obtained using expressions (12) and (13) instead of (8) by a commercial MIP solver (ILOG CPLEX 11). However, in the remaining experiments 6-25, the MIP solver could not even find an initial feasible solution within the fixed time limit. As the number of trips increases and the due dates looseness decreases, the TS approach is able to find a better result than the other ones. Indeed, on one hand the average gaps are 3%, 1.2% and 3%. On the other, if only experiments 21-25 are considered, the average gap values are 3.5%, 2.5% and 4.0%. The good performance of TSHM shows the capabilities of hybrid metaheuristics to be adapted to our problem.

5. SUMMARY

In this work, we proposed a Tabu Search approach to solve the vehicle scheduling problem in linear layout system. We developed our approach by defining the initial solution, the move, the neighborhood, the tabu list and diversification. In particular, the proposed approach implementation reflects the characterization of the scheduling problem in the linear layout. The benchmark of the considered approach has proven its effectiveness against state-of-the-art approaches.

ABSTRACT

In times of severe economic challenge, the natural reaction is to make decisions that can make an organization become as lean and focused as possible. This reaction of implementing “lean to the max” may, in fact, provide outcomes that are exactly the opposite of what is desired. This paper discusses the benefits and pitfalls associated with lean manufacturing management. These benefits and pitfalls may be seen as outcomes based on the degree to which lean is implemented. Elements of lean discussed in this paper address organizational waste, human resources, distributed design, supply chain management, customer management, and the financial system. Potential solutions and recommendations are made to help organizations remain focused on being centered as well as lean.

1. INTRODUCTION

The benefits of Lean Enterprise Management are well documented. More and more companies have embraced Lean as the only way to manage their business. While the principles of waste reduction, human optimization, distributed design, and supply chain management has served many companies very well, these benefits may alternatively lead to absolute failure. The authors previously documented the “ravages” of lean thinking taken to the limit and proposed the Temporal Think Tank (T3™) [1] as a solution.

Lean management focuses on eliminating waste (non-value-adding activities) throughout their systems. This leads organizations to better understand their customers’ needs and deliver what the customer wants exactly when they want it (Just-in-Time). Lean has led to higher quality throughout the production chain and design through evolution. Major manufacturers concentrate their expertise and judiciously outsource vital sub-components and sub-assemblies to specialists who become critical to the supply of the final product. By selective sharing of design/development, the lead (lean) organization can focus resources and competencies on a limited set of innovative ideas and reduce their direct costs for innovating many of the components in their products. What, however, happens in the event of a sea-change as described in [1], or worse yet, the failure of a vital supplier? Only by addressing various scenarios can the high-level organization hope to succeed, or even survive.

This paper explores the positive and negative aspects of a lean philosophy. Providing this foundation exposes some pitfalls in lean thinking. The current downward shift in the marketplace poses important challenges to the lean paradigm. Can companies apply lean in a shrinking economy, while focusing on innovations needed for survival? In particular, this paper suggests that organizations, to protect their value streams, begin the effective use of business system- and production-oriented T3™’s, develop more intelligent and flexible manufacturing systems, redefine values to encourage long-term, risk-taking innovation activities, and closely support suppliers along their entire value chain.

2. BENEFITS AND PITFALLS OF LEAN SYSTEMS

While the benefits of lean practices are well documented, some of the negative effects of lean on employee outcomes, work characteristics, product design, and an organization’s innovation capability have also been studied [1-5]. To offer researchers and practitioners an extensive list of the potential pitfalls in the lean thinking, we present our analysis in this section. The analysis is based on a thorough literature review in the fields of lean manufacturing, new product development, technology and innovation management, and human resource management. Case studies are also employed in our research. Besides those ones identified in literature [1-5], many more issues have come to our attention as we link the lean philosophy to other management concepts. In the following sections, we attempt to clearly spell out the key concepts of lean and discuss the associated pitfalls.

2.1. REDUCING WASTE

Waste reduction is the fundamental concept in the lean philosophy. By focusing on value-adding activities, lean enterprises actively work to identify and eliminate different kinds of waste, called *muda* in Japanese, from the system. Any activities that consume resources but do not create value will be considered *muda*, and become the subject of Kaizen (continuous improvement) events. Wastes can include designing wrong products that no customer wants, making mistakes in the manufacturing process that leads to defects, employees being left idle or waiting for deliveries during work hours, etc. The seven categories of waste summarized in [6] have a good cover of all the wastes in lean definition, and they are listed as:

- Overproducing more items than included in customer orders.
- Inventory due to increases of finished goods and work-in-process.
- Motion that does not add value to the final product.
- Waiting for any resource throughout the flow of design and production.
- Transportation or the additional movement that is not of value to the product.
- Over-processing or additional steps that do not increase the overall value of the product.
- Not being right the first time or the costs and time associated with repairing and correcting a product.

Correct identification of *muda* and successful elimination of them leads to reduced manufacturing cost, higher product quality, improved customer satisfaction, and increased profits.

However, in reducing waste and focusing on value-adding activities, a company may focus on obvious short-term benefits and ignore long-term competitive advantages. Since the return on investment for many innovations is very difficult to quantify when the ideas first take shape, especially before the potential market has been clearly identified and developed, it is very likely that those ideas, especially the ones offering particularly long-term contributions, will be considered non-value-adding and thus be cut off.

Even before ideas get generated, the time and effort that are necessary to spark innovation may also be eliminated as waste in a lean system. It should be noted that when the lean concepts were first developed in Toyota Company by Taiichi Ohno, time was set aside periodically for the worker teams to get together and suggest ways to improve the system [7]. These “creative times” are highly valuable in keeping the teams, and hence the organization, innovative and to continuously improve the manufacturing process. However, as lean practices reach the extreme, the shrinking size of the workforce and the busy schedules of employees who have multiple responsibilities will make it much harder to get workers together for formal discussions, much less casual chats that may spark innovative changes.

In addition, in order to identify non-value-adding activities, value should be clearly understood and defined. In lean thinking, it is emphasized that value can only be defined by the end users [8]. Customers’ needs and wants should be followed closely in product design and manufacturing. Any products or features that the current customers do not want will be considered *muda* since they do not generate revenues in the current market. This approach is expected to continuously and incrementally improve products and increase customer satisfaction, especially in a market pull situation. However, it may hinder radical innovations that create technology push opportunities and cause companies to stumble upon disruptive innovations. A disruptive technology is a new technology or new application that usually underperforms in area(s) most desired by the mainstream customers, at least in the short-term, but with other valuable features and great potential to develop, the technology can eventually better more established technologies and dominate the market. As noted in [9], blindly following customers’ demand may lead a
company to focus on technology development that overshoots customers’ demand and lose the market to disruptive
technologies that had been initially denied by the same group of customers. Therefore, exclusively following
customers’ definition of value and the elimination of all “non-value” adding activities can lead a lean company to
failures because customers can be wrong, or at least short-sighted.

2.2 Human Resource Management

The second keystone to the lean philosophy is to “respect the workers” since they are the knowledge resources in
the system. As discussed above, slack in lean systems are continuously identified and removed as muda. Slack on
the human resource side mean unused work time and excess workers. Increasing worker utilization and reducing
the size of the workforce usually lead to reduced manufacturing costs. However, stress is also created in the work
environment from “crazy” schedules and multiple responsibilities. In certain situations, stress may drive “creative
tensions” that stimulate employees’ creativity [10]. However, too much stress is more likely to stifle employees’
creative thinking. As noted in [11], most people cannot function effectively in a time crunch for long periods
without burning out, even if they have a sense of being on an important mission and being challenged. Therefore,
even though the jobs in a mature lean system are supposed to make employees feel important and challenged and
thus greatly respected by the company, workers will not be able to innovate when they have been under too much
stress for too long. Typically when a company becomes leaner and leaner, a naturally expected result is layoffs.
Unlike workers in Japan, where lean manufacturing originated, workers in the West do not have the luxury of a
lifetime employment guarantee. As a result, lack of job security constitutes another source of employee stress in lean
enterprises. For employees in western lean companies, a conflict exists between the fear of losing jobs and the need
to accomplish more with less people while continuously eliminating excess workers. This probably explains why
critics renamed lean manufacturing “mean manufacturing” or “management by stress [3].”

Just because of being lean, the company runs the risk of being fragile in situations when many workers call in
sick or choose to go on strike. In either case, not enough people will be there to cover the jobs; work will be delayed
dramatically and quality may suffer. With “just enough” people who are very much stressed and in many cases
pushed to the limit, a lean system can hardly respond to such emergencies.

Employees in a lean company are trained and expected to take on multiple responsibilities. Since everyone can
perform every job to some degree, the flexibility of the system is increased. During times when sales decrease,
instead of waiting for orders beside the assembly line, primary engineers and assemblers are expected to transform
themselves into salespeople and go out to talk to potential customers to create sales. However, as a tradeoff,
employees may lose special expertise as they change roles frequently. In traditional organizations, the career ladder
is designed to allow employees to gain a depth of knowledge in one special area first and then expand their expertise
[12]. It is important to develop expertise in an area since it is essential to have expertise in order to innovate in such
an area, and broad understanding of different areas will be a plus that sometimes stimulates innovations. In lean
environments, if the job responsibilities are shared too broadly and shifted too often, the employees may never get a
chance to deepen their understanding and keep up with the development of technologies in any area. This will
eventually negatively affect the capability of an organization to innovate and can even lead to a regression in
retained organizational knowledge.

One of the cases that the authors considered when examining the potential pitfalls of a lean workforce is a
university department that has been short of teaching resources for several years. To survive increasing student
enrollment with a “lean” faculty group, many members have to take the responsibility of continuously teaching new
courses, some of which are not in their direct or closely related areas of expertise. At the same time, the average
teaching load and the service load have also been increased. Time to perform research and innovate, either with their
classes or in departmental outlook has been largely taken instead by developing course materials and preparing for
lectures. The innovation rate, measured by publications in this context, can only be seen to decrease.

2.3 Distributed Design

Distributed design characterizes the product design and manufacturing strategies in lean companies. In fact,
Japanese lean car producers design and provide detailed drawings of only 30% of the parts in their cars, the rest are
distributed to its first-tier suppliers, who usually have expertise in process engineering and plant operations[7]. In
this way, the responsibilities of manufacturing are mostly shifted to suppliers. The lean producers become focused
on the overall design of product and the final assembly of parts being engineered and produced by different
suppliers. This approach agrees with the economic theory that distributing jobs to the most efficient parties increases overall social welfare. By focusing on product design and final assembly while aggressively outsourcing parts, lean companies are able to steadily decrease the unit cost of products. However, since most major parts are outsourced as a “turnkey” project to suppliers, the lean producers are barely involved in manufacturing of many, and often key, components of their products. As a result, the company’s own ability to design, debug, and improve manufacturing systems, or even large segments of their products will decrease.

For a company that wants to achieve product leadership, it is critical to maintain and strengthen its manufacturing ability. This is linked to a third cornerstone of lean: being agile where this agility helps develop from the strength of design and manufacturing knowledge and facilitates bringing innovative products to market quickly. Designing high quality products and low cost manufacturing is an important part. When incremental changes to modules/parts no longer lead to overall product improvement, the relationships among the product components and core concepts may need to be reconfigured[13]. In such a situation, manufacturing processes for new designs will need to be created, assessed, and improved. The Toyota Company in Japan tries to maintain a long-term relationship with its suppliers and helps them improve manufacturing by loaning / switching its engineers through the supplier companies. This approach promotes communication and knowledge sharing between producers and suppliers to a great degree. However, to solve the fundamental problem, a company will need a strong incentive and great commitment of time and efforts to understand and be involved in major suppliers’ manufacturing process.

Another tradeoff to distributed design when parts are mostly outsourced is that the innovations from internal product research and development (R&D) at a company may flow out to competitors too quickly, even before the company can benefit fully. Since most suppliers provide parts to multiple customers, to reduce cost, suppliers are likely to provide parts that are similar, if not the same, to each customer. Even if there are agreements in place to keep trade secrets, other customers of the same supplier may “smell” innovations from the parts or assemblies they receive or conversations with the supplier’s representatives.

2.4 SUPPLY CHAIN MANAGEMENT

In the lean supply chain, parts from suppliers arrive shortly before they are needed since excess inventories were eliminated as waste. This approach saves storage space and costs, and improves efficiencies. However, with no reserve stocks, the system will stop running if parts do not arrive on time or a faulty shipment comes. This happened in the early stage when General Motors (GM) tried to embrace the lean philosophy in its Pontiac assembly plant in Pontiac, Michigan. Since all the buffers and inventories had been removed, a failure of a shipment from its supplier, in this case the Flint plant nearby, caused the entire plant in Pontiac to shut down and they had to send the workforce home four hours early with a loss in production of product that was slated to flow to the customer [8]. Although this issue is supposed to be solved by the supporting organizational structures that are constructed, there is no guarantee that a late or faulty shipment will not happen in a mature lean system. Supply problems become more likely when financial crises affect every component of the economy, as we find today. Since large complex parts of the product are “sole-sourced” in lean-supply systems, the failure of a supplier, especially a first-tier supplier, can be fatal to the company. Strikes at different levels of the supply chain will also have a significant negative effect on production at the lean company. One need only consider the problems at GM when a supplier of airbags went into bankruptcy and no longer provide products to them, or would even release GM’s tooling to move it to a different supplier [14]. The 1998 strikes in two of GM’s part supplier factories in Flint, Michigan, that caused 26 out of 29 North American assembly plants to close down and lay off nearly half of GM’s workforce [15] is another good example that without buffers, failure of any link on the lean supply chain will cause the whole chain to fall like dominos.

One of the prime driving ideas that most companies adopt when they begin their conversion to Lean management is to consolidate their vendor list. Since there is a cost associated with keeping communication channels open to vendors, even if they are not Tier 1 or even regular suppliers, most lean companies view extra vendors as muda. Reduction in vendors can save resources; however, it can also limit innovation. One of the authors spent time with a Lean manufacturer recently and observed an unfortunate issue as the engineering staff explored a new quality process. The engineers had identified a promising new measuring device but they were unable to purchase it for testing because the vendor was not “on the approved list!”. This led to a significant delay and additional expense for bringing innovation into the company. Surely this was an unexpected, but often observed, consequence of the effect of vendor and supply chain control in lean enterprises.
2.5 CUSTOMER MANAGEMENT

In the Japanese Toyota system, a large workforce is maintained to deal with customer management. Japanese buyers usually purchase a new car about every four years, due in large part to a governmental policy that requires very expensive and very demanding vehicle inspections as a car ages. In order to maximize the total income from a customer over the long-term, the sales department in Toyota devotes a significant, and costly, effort to keep good long-term relationships with every customer[7]. Keeping every customer’s information in a database and calling them frequently will instill customer loyalty and make it difficult for competitors to gain a share in the Japanese market.

Compared with customers in Japan, people in other countries do not have to purchase new cars as often in the absence of strict government regulations dealing with the inspection of aging vehicles. Therefore, maintaining a long-term relationship with customers seems much less important in those markets. A lean system would likely view a large workforce dedicated to customer management as a waste, thus, will train and expect the customer service personnel to perform other jobs. As mentioned in [7], during a visit to the Toyota company, the authors were told that the external relationship manager was too busy to meet with them since he was doing some assembling. In the same way, the experts that used to analyze and communicate customers’ needs may be moved to other jobs and become too busy with more obvious or urgent work, including assembly. By this action in the long-term, knowledge and expertise needed to managing customer interaction will be lost.

2.6 FINANCIAL SYSTEM

While the shadow pricing strategy is used in both lean and mass production companies, lean companies tend to use it more aggressively. As shown in Figure 1, lean companies try to set the selling price much lower than the actual initial cost, in hope that by applying lean practices, the unit manufacturing cost will drop faster and more dramatically as more customers are attracted to purchase the product. It is reasoned then that profits gained later through expanded market share will soon compensate for the losses incurred in the beginning of a product’s life. Increasing sales to the point that early losses can be compensated is therefore critical for the lean company to survive. While this strategy is expected to encourage initial purchases, applying it in a shrinking market without being able to differentiate the product with superior features and total qualities will only expedite the fall of the company. Simply being cheap is not the answer to sustaining success: innovation and technological advancements are the ultimate driving forces of product leadership.

In the Japanese lean system, long-term relationships exist between the lead company and its suppliers. Besides sharing personnel, they interlock equities and depend on each other for financing which in part justifies their reliance on shadow pricing as it spreads the wealth as well as the potential losses throughout the “extended” organization. Essentially, the lead company and its suppliers are sharing the same destinies. This requires the companies to be highly supportive to each other. Otherwise, failure of one member will quickly spread the crisis to the whole group.

![Figure 1: Shadow Pricing Strategy as Employed by Lean Organizations](image-url)
2.7 SUMMARY

Table 1 summarizes the lean concepts and the potential failures that they may lead to, as discussed in the previous sections.

</table>

3. SOLUTIONS

For a company to maximize the benefits of its lean practices, special attention must be paid to the pitfalls discussed above. While it is not the purpose of this paper to offer an exclusive list of solutions, a few are suggested.

When one reviews a company that has a strong survival instinct, often we find that they have embraced the ability to be agile and flexible in their product design and manufacturing environment. This agility is linked to their innovative spirit and is vested into the establishment of independent organizations, like those espoused by the author’s in the Temporal Think Tank™ (T3™) [1]. When economic conditions become difficult, as in the current worldwide economic crisis, it is the companies who have agile philosophies that can succeed. Thus, at least as it views the future, an organization must drop strict adherence to the Lean mantra of “its muda” to carve out its future by finding time to reflect and study for products that will allow it to flourish in the recovery period that is ahead. Creating an independent organization, like T3™ [1], with a cost structure not honed to achieve high profit margin in the current market is also a solution for companies to harness disruptive innovations without affecting the lean nature of the parent company.

To cultivate an innovation-encouraging culture in a lean company, it is important to define value in the way that innovation driving activities are viewed so as not to be considered muda. Setting aside some creative times not only helps reduce job anxiety and get employees re-energized, but also provides opportunities for the employees to interact and stimulate out-of-the-box thinking. Defining value effectively also calls for a positive attitude toward risk taking. As emphasized in an interview by Jeff Immelt, CEO of General Electric (GE), it is important for an organization to make it „ok“ to take risks and devote time and efforts to certain activities that do not produce results in a short term [16]. An R&D portfolio that builds both short-term and long-term competitiveness will better prepare
a lean company to stand out in fierce competition. As an essential part of the lean system, workers should be respected and involved as much as possible in the decision making process. In this way, a sense of importance, enjoyment, and satisfaction will be provided to motivate employees’ creativities.

Given the advantage of being flexible, a lean company should be able to respond to changes more effectively if contingency plans are developed ahead of their absolute need. Therefore, besides ensuring competitiveness through continuous innovations, the company also wants to closely monitor and forecast the market demand and technology trends, assess its own competitive advantages, conduct sensitivity analysis, and generate scenario analyses. A variety of decision analysis tools are available to facilitate such activities and sharpen decision makers’ judgment [17-20]. What the companies need to do is to select and adopt suitable ones to maximize their benefits. In addition, to better cope with uncertainties and disruptions in the dynamic market environment, more intelligent and flexible manufacturing systems are needed, especially for the companies in which tooling and equipment require large capital investment. Flexible product platforms can be designed to effectively share common components and deliberately project uncertainties into flexible elements that are carryover-modified in different product families or product generations. In this way, the need of redesign as well as changes in manufacturing tooling and equipment will be minimized in an event of new product introduction. Details about the systematic process of flexible product platform design can be found in [21].

Due to the strong dependencies of a lean company on its suppliers, it is critical for the lean company to support those suppliers. This calls for more transparent financial systems and cash flows along the chain, since the system is only as strong as the weakest component of the whole chain. In the unfortunate incident stated above, with the failure of a key supplier, one can only wonder if cost control tactics by GM were not ultimately to blame in the failure. Surely, squeezing a few more cents out of the cost of the product each year for the last few years, as its market share shrank, did little to improve the sales picture for GM but could have sealed the collapse of this supplier. With better foresight this cash strapped supplier, who was likely unable to support innovation, could have been saved and could have begun to deliver even better products to GM in the future. GM could have provided assistance, perhaps by increasing its prices by a few dollars per vehicle and passing the added revenue directly back to its struggling supply chain with a very small impact of its number of sales over the short term. This would be clearly seen as a “shadow pricing” initiative that would have reaped huge benefit into the future.

Any organization, regardless of where it lies along the road to lean, can open itself to clearly explain its financial condition to its partners. It can share difficulties and build long term trust, strength, and a healthful and supportive relationship, as suggested by the Japanese Lean Manufacturers, rather than creating legal adversaries as has happened here.

Closely working with the suppliers also helps the lean company to keep up with the most recent developments in manufacturing technologies. This may require additional personnel from the lean company to work in supplier companies; however, it is critical for the company to maintain its ability in designing and debugging the manufacturing system, and to optimize the whole value chain.

4. Conclusion

Lean enterprise management aims to eliminate waste, effectively manage personnel, distribute design among entities that are best at each stage, work with the supply chain, manage customers, and wisely manage the organization’s finances. In each activity, the focus is to eliminate muda, or waste.

For each of these elements of lean, examples have been provided in this paper to warn against the zealous over-application of lean. Taken beyond a moderate, reasonable level, lean will actually decrease the organization’s ability to compete. In times of great economic stress, implementing lean management as much as possible is an understandable reaction, but it may ultimately insure the failure of the organization rather than save it. The authors have offered advice to the newly lean organization to avoid many of the pitfalls of “over zealous lean” to become a stronger competitor for having survived the on going, or in fact any, financial crisis.

A Methodology for Scheduling Part Families in Cellular Manufacturing Systems with Reconfigurable Machines

Ignacio Eguia\textsuperscript{1}, Jesus Racero, Sebastian Lozano, and Fernando Guerrero

\textbf{ABSTRACT}

Cellular Manufacturing Systems (CMS) help to reduce set-up time, manufacturing lead-time, and improve productivity and operation control, but they lack in flexibility and, thus, cannot respond to the production of any quantity of highly customized and complex products. Some degree of adaptability and flexibility can be attained using reconfigurable machines in CMS. The aim of this work is to establish a methodology for an effective working of CMS in the presence of reconfigurable machines, which consists of some machine modules which can perform different operations. Products with similar characteristics must be grouped into families. Each family requires one configuration of machines and modules to produce all the products of the family. Set-up costs must be considered to change from one family to the next one. Machines and modules have been grouped into parallel cell configurations in order to reduce lead-time and improve productivity. A mixed integer linear programming model has been developed to select the product families and their configurations, to assign each family to each cell and to sequence the assigned families within the cells by minimum costs. The model has been tested with high size problems adapted from the literature.

1. INTRODUCTION.

Current manufacturing environment becomes turbulent and uncertain and some critical requirements for a manufacturing system are essential to survive. Short lead time, more variants, low and fluctuating volumes and low prices are some of these general requirements of next generation of manufacturing systems. On the basis of changes in the strategies to meet these requirements, different types of manufacturing systems have been developed, viz. the Dedicated Manufacturing Systems (DMS), the Flexible Manufacturing Systems (FMS), the Cellular Manufacturing Systems (CMS), etc. The DMS provides profitable and cost-effective production in a stable market, but it is unable to operate effectively in the present dynamic market scenario. The FMS use expensive CNC machines with fixed hardware and software to produce a variety of products, but their implementation has not been very successful because of the lower throughput, high cost or complex design.

A CMS is based on the group technology (GT) principle of grouping similar parts into families. In these manufacturing systems, machines are grouped into several cells, where each cell is dedicated to process one or more part-families. A CMS helps in reducing work-in-process, set-up time, manufacturing lead-time and material handling, and improve productivity. However, a CMS lacks in flexibility and, thus, cannot respond to some requirements such as dynamic part mix and demand variation. To reduce the level of performance deterioration under these dynamic manufacturing environments, some degree of adaptability can be attained using Reconfigurable Machines (RM) within a CMS. A RM is a modular machine with some basic and auxiliary machine modules. When the auxiliary modules are changed, different operations can be performed on the new machine configuration.

Usually a RM has been used as part of a Reconfigurable Manufacturing System (RMS). Koren et al. [1] defines a RMS as “a manufacturing system designed at the outset for rapid changes in structure as well as in hardware and software components in order quickly to adjust production capacity and functionality within a part family in response to sudden changes in market or in regulatory requirements.” Xiaobo et al. [2] considers a RMS as a
manufacturing system configured to produce a family of products that share some similarities. Time reduction for introducing new products to the market with high quality and low cost is a duty for enterprise survival in this new scenario. The manufacturing system must be able to yield different batch sizes from different product types, with the exact capacity and functionality in each case.

This research aims at the development of a methodology for an effective working of CMS in the presence of reconfigurable machines. To achieve this goal, the proposed methodology consists on three steps (figure 1): grouping products into families, selecting the appropriate cell for each family and scheduling the families for each cell. The requirements and needs for products in CMSs with reconfigurable machines are first discussed to group products with similar characteristics. Then, the development of a mathematical model is proposed to design and scheduling the best cost-effective cells. Finally, the main conclusions are presented.

The unique method in the literature applied specifically for CMS with reconfigurable machines is from Pattanaik et al. [3], who present a methodology to design machine cells using modular machines using certain characteristics of reconfigurable manufacturing. It is based on the clustering approaches used in Group Technology, to group machines into cells but in their research products are not grouped into families and modules are not assigned to the designed cells.

2. GROUPING METHODOLOGY.

In a CMS, machines are grouped into several cells, where each cell is dedicated to a particular part family and their objective is to maximize the cell independence. The identification of part families and machine groups is commonly referred to as cell formation. Numerous approaches have been reported for cell formation. A sequential procedure has been used in the present methodology to determine the part families first, followed by machine assignment.

The developed methodology for grouping products into families is based on hierarchical clustering agglomerative methods. The starting point for applying hierarchical clustering is to collect a data matrix where the
columns are the products to be cluster-analyzed and the rows of which are some attributes that describe the products. Reconfigurable machines are designed to possess a set of key characteristics, such as, modularity, scalability, integrability, convertibility and diagnosability [4]. In a previous research [5], some of these characteristics have been adapted to obtain the data matrix, and then calculating a resemblance matrix coefficient to measure the similarity among all pairs of products. Finally, using a clustering method, the values of the resemblance coefficient have been processed. As a result, a dendogram or inverted tree structure is obtained, that shows the hierarchy of similarities among all pairs of products, and the different grouping that can be formed depending on the similarity of products within a family. From the dendogram, the selection of families is made based on any criterion. Figure 2 shows an example of dendogram for four parts or products. There are four sets of families, indicated by four levels. The first one \((L=1)\) is composed of four families, each of which is composed of one product. The second one \((L=2)\) is composed of three families \((B-C), (A)\) and \((D)\), the next level \((L=3)\) is composed of families \((B-C)\) and \((A-D)\), and the last one is composed of one family.

![Dendogram for parts A, B, C and D results](image)

If the number of cells is a data, a trivial solution consists of selecting the level with exactly the same number of families. Then each cell is dedicated to produce all the products of each family. However, with reconfigurable machines the costs associated to change from a family to the next one are low and it may be “cheaper” assigning two or more families to one cell than only one family per cell.

The manufacturing system has to adapt its capacity and functionality to the production of each family. Therefore, in each system’s configuration, the capacity of the machines and the utilisation of their functionalities are parameters to optimise. A RMS tends to the usage of the full capacity and functionalities of the installed machines. The identified parameters have to be implemented with the same measurement: the cost. Thus, the key parameters for the product families’ selection and scheduling in RMSs are: the changeover (reconfiguration) cost, the cost of the under-utilisation of the machines’ capacity, and the cost of the under-utilisation of the machines’ functionalities [6].

This problem of selection and scheduling the product families at each level of the dendogram is quite similar to the Travelling Salesman Problem (TSP) which seeks to identify a Hamiltonian path (a tour) that minimise the distance travelled by the salesman. The goal of minimising total distance can be changed into minimising total cost or time. At first glance, several similarities with our problem arise. First, cities in TSP can be compared to product families in RMS. Second, the goal in TSP is to minimise the total distance/cost/time required for completing the tour, whereas in RMS the goal is to minimise the total cost. Finally, the salesman in TSP has to finish in the initial city, whereas a RMS is configured for producing the first family when the last one has finished. It is well known that the TSP is a combinatorial optimisation problem of NP class. Thus, the selection and scheduling of product families in RMS is a NP class problem too. In our case, with more than one cell, the problem of selecting the families, assigning to each cell and scheduling the selected families at each cell is then similar to the Multiple Travelling Salesman Problem (mTSP), which requires determining the cities to assign to “m” salesman as well as the optimal ordering of the cities within each salesman’s tour (figure 3). Thus, this problem is more complicated than the TSP.
In this paper, an integer programming formulation is proposed to assign, select and schedule part families in a cellular manufacturing system with reconfigurable machines based on a three-index formulation of Christofides et al. [7].

3. INTEGER PROGRAMMING FORMULATION.

For the selection and scheduling of the product families, a mathematical model that includes the cost parameters expressed above is required. This model is based on four assumptions: the capacities of the machines are considered infinite, there is only one process plan for producing each product, each machine has its own basic and auxiliary modules, and the number of cells is known. The notation used for model development (indices, parameters and variables) is shown in Table 1.

<table>

| \( N_l \) | Number of families to produce in level \( l \), so \( N_l = |F_l| \) |
| \( R_{ijl} \) | Reconfiguration’s cost from family \( i \) to family \( j \) in level \( l \) \( (i \in F_l + \{0\}; \ j \in F_l + \{0\}; \ i \neq j; \ l = 1, \ldots, L-1) \) |
| \( H_0 \) | Cost of the under-utilisation of machines’ resources while producing family \( i \) in level \( l (i \in F_l) \) |
A Methodology for Scheduling Part Families in Cellular Manufacturing Systems with Reconfigurable Machines

\[ C \text{ Number of cells} \]

**Variables**

- \( T_{ijl} \): 1 if family \( i \) is produced just before family \( j \), within level \( l \) in cell \( k \) (\( i \in F_l + \{0\}; \ j \in F_l + \{0\}; \ i \neq j; \ l = 1, \ldots, L - C + 1; \ k = 1, \ldots, C \))
- \( K_l \): 1 if all the families within level \( l \) are produced (\( l = 1, \ldots, L - C + 1 \))
- \( U_{il} \): \( \geq 0 \), auxiliary variables for avoiding subtours (\( i \in F_l; \ l = 1, \ldots, \min(L - 2, L - C + 1) \))

The objective is to select the level of the dendrogram that minimises both the cost for changing between families (changeover costs), and the cost for the under utilisation of the resources of each machine while producing those families.

The constraints to take into account are:

1. Only one of the levels in the dendrogram is selected (constraint 0).
   - All the families from the selected level will be produced, and none of the families will be produced for the rest of the levels. Besides, the number of variables for the changeover of the production system (T) must be equal to the number of families (constraints 1).
2. In each level, the families are manufactured one by one following a production order, and at the end the system is configured for manufacturing the initial family. Variables T can exist before one family and after one family (constraints 2) only. The same occur in the TSP (Travelling Salesman Problem).
3. Each cell is used exactly once (constraints 3). In the model, an initial configuration \( \{0\} \) has been defined, so that the system starts and finishes at this initial state.
4. Subtours within each level are not feasible. Therefore, the Miller-Tucker-Zemlin constraints [8] are introduced. This set of constraints avoids that, as for example, five families were produced in two different ways, as: 1-2-3-1-… and 4-5-4-… (constraints 4).
5. Sign constraints of binary variables (T, and K) and auxiliary variables (U) (constraints 5.x).

Therefore, the mathematical model is the following:

\[
\text{Min } \sum_{l=1}^{L-C+1} \left( \sum_{i \in F_l + \{0\}} \sum_{j \in F_l + \{0\}} \sum_{k=1}^{C} R_{ijl} T_{ijl}^k \right) + \sum_{l=1}^{L-C+1} K_l H_{il}
\]

subject to

\[
\text{(0): } \sum_{l=1}^{L-C+1} K_l = 1
\]

\[
\text{(1): } \sum_{j \in F_l + \{0\}} \sum_{k=1}^{C} T_{ijl}^k = K_l \quad : l = 1, \ldots, L - C + 1; \quad j \in F_l
\]

\[
\text{(2): } \sum_{j \in F_l + \{0\}} \sum_{k=1}^{C} T_{ijl}^k - \sum_{j \in F_l + \{0\}} \sum_{k=1}^{C} T_{ijl}^k = 0 \quad : i \in F_l + \{0\}; \quad l = 1, \ldots, L - C + 1; \quad k = 1, \ldots, C
\]

\[
\text{(3): } \sum_{j \in F_l} \sum_{k=1}^{C} T_{ijl}^k = K_l \quad : k = 1, \ldots, C; \quad l = 1, \ldots, L - C + 1
\]

\[
\text{(4): } (N_l + 1) \cdot \sum_{k=1}^{C} T_{ijl}^k + U_{il} - U_{jl} \leq N_j \quad : i \in F_l; \quad j \in F_l; \quad j \neq i; \quad l = 1, \ldots, \min(L - 2, L - C + 1)
\]

\[
\text{(5.1): } T_{ijl}^k = \{0,1\} \quad : i \in F_l + \{0\}; \quad j \in F_l + \{0\}; \quad j \neq i; \quad l = 1, \ldots, L - C + 1; \quad k = 1, \ldots, C
\]

\[
\text{(5.2): } K_l = \{0,1\} \quad : l = 1, \ldots, L - C + 1
\]

\[
\text{(5.3): } U_{il} \geq 0 \quad : i \in F_l; \quad l = 1, \ldots, \min(L - 2, L - C + 1)
\]
As the number of families within level \( l \) (\( N_l \)) is \( L-l+1 \), then the number of variables and constraints may be calculated by the number of levels (or products) \( L \) and the number of cells \( C \).

Comments:
1. The selection of families can be solved calculating the cost of each level in the dendogram, and the level with the lowest cost will be selected. Thus, all the possible solutions are evaluated. A high number of products involve lots of calculations, which may require years for solving.
2. All the families are manufactured in sequential order, starting and ending with a predefined configuration.
3. The problem is highly complex (NP-Hard), and therefore the number of operations for the resolution of the model grow exponentially with the number of products. Therefore, the use of heuristic methods is suggested.
4. In the model, the capacity of the machines have been considered unlimited. Thus, the inclusion of the capacity of the machines and the product demands in future models are required.

4. EXPERIMENTAL RESULTS.

In order to solve the model, costs have to be calculated. As shown in Table 1, the model presents two different costs: the cost of the reconfiguration among families (R), and the cost of under-utilisation of the machine resources (H). Cost calculation is improved if it is decomposed in parameters. On one hand, the reconfiguration costs have been decomposed in three different parameters: \( \alpha_R \) if a module of machine is swapped, \( \delta_R \) if a machine is incorporated in the production system, and \( \gamma_R \) if a machine is removed from the system layout. On the other hand, the costs of under-utilisation of machine resources have been decomposed in two parameters: \( \alpha_N \) if a module of machine is not utilised, and \( \delta_N \) if a machine is not used when manufacturing a product. The costs assigned to those parameters are previously estimated. The estimation is an issue of great importance, because different costs involve the selection of different families.

Due to the lack of existing reconfigurable systems, some problems from the literature regarding Cellular Manufacturing Systems (CMSs) have been modified in order to be taken as CMS with reconfigurable machines problems. Data in CMS problems are machines and parts. Machine’s modules have been added. Table 2 shows the size of the different problems implemented regarding number of products and variables, and results as CPU time (in seconds) and Costs. Each problem has been solved with 1, 2 and 3 cells.

</table>
The CPU time required for solving the proposed model is increasing with the number of products and with the number of cells. And the operational costs decrease with the number of cells. Those problems have been solved with the linear programming software CPLEX v.10, and using a CPU at 1.6 GHz PC. Figure 4 presents the variation of CPU time with the number of products for all the problems referred in Table 2.

In the figure 4, the tendency of CPU time with the number of products is increased hardly when the number of products is higher than 40 and using 3 cells. Therefore, the model is appropriate for problems with 40 products or less. This result shows that heuristics must be developed for solving problems with more than 40 different products.

5. CONCLUSIONS.

This research has presented a methodology to solve the cell formation and scheduling of part families in the presence of reconfigurable machines. The methodology uses agglomerative techniques of hierarchical clustering that were developed for the needs of the CMSs, conveniently modified in order to take into consideration the requirements of RMSs. For the selection of the product families, the assignment of those families to cells and the schedule in each cell, a mathematical model has been developed based on the identification of the key parameters that influence that selection. Finally, the model has been validated with 16 different problems from the literature, and their results have proved the need for developing heuristics when the problem presents more than 40 products and 3 cells.

Scheduling of production orders with assembly operations and alternatives

Krzysztof Kalinowski*

ABSTRACT
The problem of scheduling in flexible production systems is considered in this paper. The model of the scheduling system in which both machining processes and assembly operations are carried out, where there are alternative resources. Production order is described by multivariant technological process – a set of technological processes for the same product, which differ in technology, type of operations, treatments and operation times. Production orders with assembly operation are divided into single processes. The general scheduling procedure with searching best operation variant on the basis of the multivariant technological processes is also described. Time and cost based objective function is used for evaluation of a set of possible solutions. The proposed method can be used for searching acceptable solution, especially in cases, when it is not possible to find optimal solution.

1. INTRODUCTION
The increasing competition in the market and a balanced level of technology are forcing companies to use modern methods of organization of production processes. Adequate arrangements for the production flow lead to minimizing production costs, have a significant impact on the price of the product and allow the timely execution of orders. When creating a production schedule, it is necessary to use a data derived from both the organizational (dates, quantities – from MRP/ERP systems) and the technical and technological production preparation (structures of products, constructions and technology – CAD/CAM systems). Therefore, appropriate cooperation between these departments in an enterprise is required.

Before accepting a new order and taking actions connected with production, the main problem is to answer quickly the following question: Can a new order be realized according to the clients’ expectations, in the same quality and quantity, and a fixed period of time, with known constraints of resource consideration? Complexity of the problem of analysing all organisational variants makes it practically impossible to solve it in quantitative sense – to obtain the optimal solution in satisfactory time. For the same reason, it is also difficult to solve the problem of determining an acceptable production flow - that is, in qualitative sense.

Technological capabilities of manufacturing systems allow the creation of many different technological processes for the same item. The differences may relate to both technology implementations, the order of implementation of certain procedures (operations) and times (duration of the treatments, the setup times, etc.) related to the possibilities of resources, used tools and equipment. The technological process with more than one variant of the implementation in the production system is defined as the multivariant technological process. The current situation in the production system and a set of evaluation criteria in a particular situation should help in deciding on the selection of the best possible option for execution. The traditional approach to the design of technological processes with optimization of a fragmented approach, ignoring alternatives, significantly reduces the flexibility of its implementation. Multivariant technological processes development, under the conditions without computer support, may prove to be too time-consuming and unprofitable, especially when a large number of possible variants can be obtained. The CAPP systems (Computer Aided Processes Planning) do not have these restrictions.

Manufacturing systems with a large number of machines, in which both machining processes and assembly operations are carried out, where there are alternative resources, are commonly encountered in industry. For such systems, however, it is not possible to develop a schedule by using methods which guarantee obtaining the optimal solution. The existing solutions are based on the use of heuristic methods, dispatching rules, genetic algorithms, and hybrids.

2. THE MODEL OF PRODUCTION SCHEDULING

The discrete manufacturing system with concurrent, multi-assortment production is considered. The base of the production control is a schedule. Presented model satisfies the following basic assumptions:

- there is flexible job shop configuration of the production system,
- there is no limitation of work in progress stores capacity,
- the technological process of a product is considered as a multi-level configuration of machining and/or assembly operations,
- processes that are realised in the system may have more than one production route, determined by multivariant technological process.

Production system \( Ps \) is described by set of machines and set of production orders:

\[
Ps = (M, Po)
\]

where, \( M \) = set of machines, \( M = \{M_1, M_2, ..., M_h, ..., M_I\} \), \( I \) = number of machines; \( Po \) = set of production orders, \( Po = \{Po_1, Po_2, ..., Po_p, ..., Po_J\} \), \( J \) = number of orders.

Machine \( M_i \) is determined by:

\[
M_i = (C_i, a_i)
\]

where, \( C_i = \) calendar of availability periods of machine \( M_i \), \( a_i = \) type of machine.

Calendar gives the timetable including free periods of a machine for assigning operations. Type of machine is a feature describing machine ability for execution of group of specific operations. The production system contains \( h \) types of machine \((1 \leq h \leq I)\).

A production order describes a single product (or bath), and consists of one (in case of machining) or more processes (e.g. machining and assembly). Each assembly operation divides a production order between processes (subprocesses of an order). A production order has the following parameters:

\[
Po_j = (C_j, r_j, d_j, pr_j, b_j)
\]

where, \( C_j = \) set of precedence constrains of processes, \( r_j = \) release date, \( d_j = \) due date, \( pr_j = \) priority, \( b_j = \) batch size.

Set of processes precedence constrains defines relations between processes of a given production order. It can be described as:

\[
C_j = \{(P_{k1,j},P_{k2,j}), (P_{k2,j},P_{k3,j}), \ldots \}
\]

where, \( P_{k1,j} = \) process of production order \( P_j \) that preceded \( P_{k2,j} \), \( P_{k4,j} \) preceded \( P_{k3,j} \), \( k_1, k_2, k_3, k_4 = \) processes numbers, \((1 \leq k1 \leq k2 \leq k3 \leq k4 \leq Kj)\), \( Kj = \) amount of processes of order \( Po_j \).

An example of an order structure of a product with assembly operations is shown in figure 1. The table shows pre and post conditions of an order. The order consists of five processes. In the production system first the \( P_{3,1}, P_{4,1} \) and \( P_{5,1} \) should be executed, next \( P_{2,1} \) and next \( P_{1,1} \). First operations of \( P_{2,1} \) and \( P_{1,1} \) are assembly operations. In this case, set of processes precedence constrains is following:

\[
C_I = \{(P_{2,1,1},P_{1,1,1}), (P_{3,1,1},P_{2,1,1}), (P_{4,1,1},P_{2,1,1}), (P_{5,1,1},P_{1,1,1})\}
\]
Scheduling of production orders with assembly operations and alternatives

When multivariant technological processes are used, a process may have more than one variant of realisation (figure 2). It can be described as a graph:

\[ G_k = (V_k, D_k, \phi) \]  

where, \( G_k \) = \( k \)-th multivariant technological process, \( V_k \) = ordered set of machining states (nodes in the graph), \( D_k \) = set of all possible operations (edges in the graph), \( \phi \) = relations,

\[ V_k = \{S_{k1}, \ldots, S_{ks}, \ldots, S_{sk}\} \]  

A state of the product \((S_{sk})\) at any time of the production process is defined by a set of states of each elementary treatment:

\[ S_{sk} = (s_{k1}, s_{k2}, s_{k3}, \ldots, s_{kf}, \ldots, s_{kF}) \]  

where, \( S_{sk} \) = \( sk \)-th state of \( k \)-th process realization, \( s_{kf} \) – state of \( kf \) treatment, \( s_{k}\in \{0,1\} \), \( (kf = 1,\ldots,kF) \), \( F \) – amount of different states of process realization.

A state of the product description allows the identification of the state during the process implementation by identifying which of the elementary treatment has already been worked, and which are not. A set of all possible operations is described by:

\[ D_k = \{O_{i1,k}, O_{i2,k}, \ldots, O_{i3,k}\} \]  

where, \( O_{i2,k} \) = an operation of process \( P_i \) realized on machine \( M_{i2} \), \( i, i2, i3 \in \{1,\ldots, I\} \).

A process is represented by subset of operations:
Number of operations for realizing the process \( P_k \) must not be constant. It depends on selected path in the graph \( G \) (selected variants of operations). An operation variant is described by:

\[
O_{i,k} = (tb_{i,k}, t_{i,k}, ts_{i,k}, c_{i,k})
\]

where, \( tb_{i,k} = \) beginning time, \( t_{i,k} = \) operation time, \( ts_{i,k} = \) setup time, \( c_{i,k} = \) cost of operation variant.

3. SCHEDULING PROCEDURE

The procedure of creating a new schedule is shown in figure 3. The first step is to select a scheduling algorithm from a set of available algorithms. A scheduling algorithm is understood as a priority rule that organizes the processes according to a specific index. Each algorithm uses its own indicators, based on the parameters of the processes, their operations, deadlines, etc. Processes are then inserted into the schedule according to their priority and may be inserted according to the forward or backward scheduling method. In case of forward scheduling method the operations of a process are placed to a schedule sequentially from first to last, and the time they start is restricted by release time of the process or the completion time of previous operation. This method is used when a process should be made as soon as possible. The method of backward scheduling inserts operations of a process in order from last to first, and the time when an operation should be finished is restricted by due date of the process (last operation in a process) or beginning time of the next operation (the next operation in the technological process). This method is used most often when too early execution is not recommended (e.g. limited storages capacity, freezing of capital - losses due to storage of materials, reducing the period of usefulness, product deterioration).

Different variants of the operation are analysed in the next step of the scheduling procedure. The way of selecting the appropriate option is to schedule temporarily each possible operation variant and compare results. The best variant of operation (that determines the current production route) can be selected by the following criteria: \( \min \) cost, \( \min \) operation time, setup time, beginning/finishing time of operation. Generally, the objective is expressed by:

\[
\min_t \left( w_1 z_{i,k}^{tb} + w_2 z_{i,k}^t + w_3 z_{i,k}^{tr} + w_4 z_{i,k}^c \right)
\]

where, \( z_{i,k}^{tb}, z_{i,k}^t, z_{i,k}^{tr}, z_{i,k}^c = \) normalized coefficients of operation variant \( (O_{i,k} \neq \emptyset) \), \( w_1 - w_4 = \) weights.

Coefficient of starting time depends on the method of scheduling (equations 12 and 13):

\[
z_{i,k}^{tb} = \frac{tb_{i,k}}{\max_i \{tb_{i,k}\}}, \text{ in case of forward scheduling}
\]

\[
z_{i,k}^{tb} = \frac{\min_i \{tb_{i,k}^{sp} + t_{i,k}\}}{tb_{i,k}^{sp} + t_{i,k}}, \text{ in case of backward scheduling}
\]

After inserting all the operations of a process, the starting times (forward scheduling) or finishing times (backward scheduling) of associated processes are corrected. If all associated processes are scheduled, the next order is taken into consideration. Next, a complete schedule is evaluated using a set of criteria.

4. Multicriteria Evaluation

If as a result of scheduling is obtained more than one acceptable solution, it is necessary to carry out the evaluation and selection of solution for implementation. In real manufacturing systems there is more than one criterion that should be considered, so production schedule should be evaluated using set of criterions. To assess, taking into account more of the criteria, the application of multicriteria evaluation of the potential solutions is required. Method of determining the best variant of the schedule should take into account the value of time and cost based criterions for a specific decision-making situation.

In the proposed method of multicriteria evaluation of a schedule are the following steps:

- determining a set of criteria for evaluation,
- assigning the weights for each criterion,
- calculation of sub-ratings (for each criterion),
- calculation of the total assessment – aggregation of partial ratings.

The evaluation criteria may have different nature: deterministic, probabilistic or fuzzy. In the present work considers only deterministic criteria. A set of evaluation criteria, used in a given situation, is a subset of all available criteria (K):

\[ K \subset K_w \]

\[ K_w = \{K_1, K_2, ..., K_r, ..., K_R\} \]

where, \( K = \) set of criteria selected for evaluation, \( K_w = \) set of all available criteria, \( R = \) number of criteria.

The basic evaluation criteria adopted in the presented model are minimizations of: makespan (\( C_{\text{max}} \)), mean completion time (\( \bar{C} \)), maximum flow time (\( F_{\text{max}} \)), mean flow time (\( \bar{F} \)), maximum lateness (\( L_{\text{max}} \)), mean lateness (\( \bar{L} \)), maximum tardiness (\( T_{\text{max}} \)), mean tardiness (\( \bar{T} \)), maximum earliness (\( E_{\text{max}} \)), mean earliness (\( \bar{E} \)) and cost criteria.

For the selected evaluation criteria weighting coefficients (\( g_r \)) are established. Weighting coefficient determines the impact of a criterion for the final evaluation. After that, schedules are evaluated separately by each of the selected criteria, to determine the partial evaluations. The overall evaluation of a schedule is calculated by aggregating its partial evaluations. The best schedule is obtained from following objective:

\[ \min \sum g_r u_{r,e} \]

where, \( u_{r,e} = \) partial evaluation of the schedule \( H_e \) (\( 1 \leq e \leq E \)) according to the criterion \( K_r \), \( E = \) the number of created schedules.

5. Summary

The paper presents a model of a production system and the general procedure that enable creating an acceptable schedule. It can be used in most real production systems – as a solution at scheduling or new order verification stage. It is based on the idea of method of technological and organisational processes planning integration. The proposed solution is dedicated for enterprises that realise multi-assortment and changeable production. In enterprises, the validity of orders is generally known (orders have fixed priorities). This constraint allows abandoning the application of scheduling algorithms and focusing on searching the set of possible options for finding the best way of order realization. The development of the multivariant technological processes at the planning stage improves the process of scheduling and coordination of processes flow in the system in case of changeable conditions of production.

Determination of the solutions in changing external conditions, causing changes in the value of the input parameters, requires adequate organization of the scheduling system. An essential condition for generation of correct solutions in a short time is a quick access to required information. Therefore, the scheduling systems should not
operate separately, but must be integrated with databases of other systems (such as system monitoring, control, planning, management, etc.). In the present work, many important issues related to rescheduling are not taken into account, e.g. delays of schedule implementation that made it out of date even before its introduction. It is very important in designing and implementing a scheduling system in real manufacturing. It is forecasted in further researches.

Effect of Axial and Radial Velocities on Solids Mass Flow Rate Measurement

Jianyong Zhang*, Bin Zhou**

**School of Energy and Environment, Southeast University, Nanjing, China

ABSTRACT

In coal powder flow transportation and combustion, powder mass flow rate is a key parameter to be monitored and controlled. Electrostatics is one of the techniques used for such task with its non-intrusive, robust and low cost natures. The passive electrostatic meters measure charge induction on the detecting electrodes. As it is known that the induced signal is not only dependent on the solids mass flow rate, but also affected by solids velocity, however the velocity of particles referred to by far is the axial velocity. In reality, the solids velocity is a vector, its projections in both the radial and tangential directions also need to be investigated. This paper analyzes the dynamic sensitivity of ring-shaped electrostatic sensors using finite element method (FEM), and investigates the influence of the axial and radial velocities on the induced signal on the electrodes.

Keywords: electrostatic sensors, spatial sensitivity, velocity vector

1. INTRODUCTION

In pneumatically conveyed solids flow, electrification occurs due to friction, collision and separation between particles and between particles and pipe wall [1, 2]. Many factors, such as particle shape, particle size, coarseness of the inner surface of pipe wall, chemical composition of material, travel distance of particles, humidity, flow profile and solids velocity affect electrification process and thus charges carried by particles [3]. Although electrostatic charging creates problems for industries [4-7], it has also found various applications [8-11]. It is well known that the electrostatic technique has been employed to measure gas-solids flow [12-14], which is the subject to be discussed in this paper. The ring-shaped electrostatic sensors can be classified into two types according to probe (electrode) construction, the flush-mounted sensor and the lined sensor. A “flush-mounted” sensor, depicted in Fig.1 has its inner surface exposed to flow and is mounted flush with inner pipe wall [15]. This simple configuration offers high sensitivity to the charge carrying particles. In contrast, there is an insulator such as a ceramic tube inside a “lined sensor”, the electrode of such sensors has no direct physical contact with flow. In this paper, the analyses are based on the flush mounted sensors.

The axial velocity of charged particles has been measured using the cross correlation method [15] or the spatial filtering method [19] successfully. However the axial velocity provides only the mean velocity of the solids along the pipe axis. Consider any individual particle, or a small volume of air-solids mixture, its velocity is actually a vector due to the turbulent motion of particles. The velocity vector can be projected in the axial, radial and tangential directions in a column coordinate reference system. It has long been known that the solids velocity affects the charge induction on the electrode; obviously, it is inadequate to consider axial velocity only. The main purpose of the research presented in this paper is to establish the relationship between the velocity vector and the sensor’s output to study the sensing mechanism of the flush-mounted ring-shaped electrostatic sensor for air solids flow measurement. It is concluded that the dynamic sensitivity of a ring-shaped electrostatic sensor depends upon the amount of the charge carried by particles, the locations of charged particles, as well as on the velocities in both radial and axial directions.

2. Simulation based on 3-D FEM

2.1 Configuration of electrostatic sensor

Fig.2 (a) shows the configuration of a flush-mounted electrostatic sensor comprised of a short spool piece and a ring probe. The ring probe is surrounded by an insulator layer preventing it from conductive contact with the pipe wall as shown in Fig. 2 (b). The grounded metal pipe wall acts as an electrostatic screen naturally. The micro-column inside the pipe in the above figure represents a charged element, which can be regarded as a group of particles evenly dispersed in this column. The size of the element has to be small enough so that it can be regarded as a charge source surrounded by

* Corresponding author: Tel.: (0044) 1642-342546; Fax: (0044) 1642-342401; E-mail: j.zhang@Tees.ac.uk
the medium of uniform permittivity.

2.2 Mathematical model
The purpose of modeling is to find the relationship between the sensor’s output voltage and the amount of charge carried by an element, its location and its velocity. The modeling is based on electrostatic theory, and the magnetic field due to moving charged particles is ignored. The electrostatic equilibrium system is governed by Poisson equations under the given boundary conditions,

$$\nabla \cdot \varepsilon \varepsilon_0 \varepsilon (x, y, z) \nabla u(x, y, z) = \nabla \cdot D(x, y, z) = -\rho(x, y, z)
$$

$$u(x, y, z) \Big|_{(x, y, z) \in \Gamma_p} = 0$$

$$u(x, y, z, t) \Big|_{(x, y, z) \in \Gamma_e} = \text{const}$$

$$E_{\infty} = 0$$

where \(u(x, y, z)\) is the potential distribution. \(\Gamma_p\) represents the inner surface of the grounded pipe with zero potential, \(\Gamma_e\) is the floated ring probe, and its potential value can be regarded as a constant if a charge amplifier is connected to the electrode, which is commonly used for signal conditioning in electrostatic sensors. \(\rho(x, y, z)\) is the charge density distribution, \(\varepsilon_0\) and \(\varepsilon(x, y, z)\) are the permittivity in free space and relative permittivity distribution of particulate material respectively. \(D(x, y, z)\) is the electric flux distribution, \(E(x, y, z) = \varepsilon_0 \varepsilon (x, y, z) E(x, y, z)\). \(E(x, y, z)\) denotes the electric field strength, \(E_{\infty}\) is the electric field strength at the infinite point, \(E_{\infty}=0\). According to the electrostatic theory, if the distribution of relative permittivity \(\varepsilon(x, y, z)\) and charge density \(\rho(x, y, z)\) are known, the one and only one solution exists under the given boundary conditions to Equation (1). Thus, the distributions of \(D(x, y, z)\) and \(E(x, y, z)\) can be found, and the induced charge on the ring probe are given by,

$$Q = \int_S D(x, y, z) \cdot ds = \varepsilon_0 \int_S \varepsilon(x, y, z) \cdot E(x, y, z) \cdot ds$$

where \(S\) is the surface of the ring probe.

Consider the complexity of gas-solids flow, the flow pattern or particulate material distribution is capricious, the analytical solution to Equation (1) can hardly be found. The 3-D finite element analysis method is used to obtain a numerical solution instead.

For the 3-D finite element analysis, an equivalent integral form of Equation (1) can be expressed as follows, where \(F(u)\) is known as the “energy function”.

$$F(u) = \int_V \varepsilon \left( \frac{\partial u}{\partial x} \right)^2 + \left( \frac{\partial u}{\partial y} \right)^2 + \left( \frac{\partial u}{\partial z} \right)^2 - \rho u \right) \ dx \ dy \ dz = \min$$

$$u(x, y, z) \Big|_{(x, y, z) \in \Gamma_p} = 0$$

$$u(x, y, z, t) \Big|_{(x, y, z) \in \Gamma_e} = \text{const}$$

$$E_{\infty} = 0$$

The „Tetrahedron element“, depicted in Fig. 3, is used to discretize the whole field due to its simple coefficient matrix and adaptability to sophisticated field shape.

The relation between the potential anywhere inside the tetrahedron volume, \(\tilde{u}(x, y, z)\) and the potentials at its four vertexes, \(u_i\) \((i=1,2,3,4)\) can be expressed by the interpolation function:

$$\tilde{u}(x, y, z) = \sum_{i=1}^{4} N_i^e u_i$$

where \(N_i^e\) is the shape function.

After discretization and interpolation are processed, the total energy function \(F(u)\) of the volume can be obtained from that of individual element, and then the finite element equations can be constructed in the following way:

Dividing the entire volume of the system into \(e_0\) elements and \(N_0\) nodes, the total energy function \(F(u)\) can be expressed as...
$F(u) \approx F(\bar{u}) = \sum_{e=1}^{e_0} F_e(\bar{u})$ \quad (5)

where $F_e(u)$ is the energy function for each tetrahedron element.

Equation (3) can be solved by finding the extremum of $F(u)$. Equation (6) provides a necessary condition for $F(u)$ to be the extremum.

$$\frac{\partial F}{\partial u_i} = \sum_{e=1}^{e_0} \frac{\partial F_e}{\partial u_i} = 0 \quad (i = 1, 2, \cdots, N_0) \quad (6)$$

The discretization of equation (3) to each element results in,

$$F_e(u) \approx F_e(\bar{u}) = \int \left\{ \frac{\epsilon}{2} \left[ \left( \frac{\partial \bar{u}}{\partial x} \right)^2 + \left( \frac{\partial \bar{u}}{\partial y} \right)^2 + \left( \frac{\partial \bar{u}}{\partial z} \right)^2 \right] - \rho \bar{u} \right\} \, dx \, dy \, dz \quad (7)$$

where $V_e$ is the volume of an element.

Substitute $\bar{u}(x, y, z)$ with $\sum_{i=1}^{4} N_i^e u_i$ based on equation (4), the partial differentiation of $F_e(\bar{u})$ becomes,

$$\begin{bmatrix} \frac{\partial F_e}{\partial u_i} \end{bmatrix} = [K_e] [u] - [P_e] = 0 \quad (i = 1, 2, \cdots, n_0) \quad (8)$$

The coefficients matrix $[K]$, for each element is symmetrical. For the field divided into $e_0$ elements and $N_0$ nodes, matrices $[K], [P], [u]$, can be expanded into $[\tilde{K}], [\tilde{P}], [\tilde{u}]$, the total coefficient matrices for the whole volume, are:

$$[\tilde{K}] = \sum_{e=1}^{e_0} [K_e], \quad [\tilde{P}] = \sum_{e=1}^{e_0} [P_e] \quad (9)$$

From the above, the finite element equations can be expressed as

$$[\tilde{K}] [\tilde{u}] = [\tilde{P}] \quad (10)$$

For any given boundary conditions, the solution of equation (10) can be obtained.

The condition of charge equilibrium needs to be satisfied to the best in the numerical simulation, ideally the charge $Q$, carried by the charged element should be balanced by the sum of $Q_p$ and $Q_r$, the induced charge on the pipe wall and on the ring probe respectively. That is to say $(Q_p + Q_r)$ has the same magnitude as $Q_e$, but with opposite polarity. However, restricted by the computation resource, there have to be compromises between the calculation accuracy and the simulation length of the pipe. The length used in this paper is 6 times the internal radius of the pipe, $l=6R$, which can guarantee the accuracy without putting a heavy burden on the computation.

The finite element meshes for the sensor are depicted in Fig.4. Fig. (4) (a), (b) and (c) illustrate meshes on the pipe, ring probe and charged element respectively. Fig.5(a) shows that the local potential distribution is characterized spherically symmetrical with regard to the charged micro-column positioned in the geometry center of the pipe; (b) shows the distribution of electrical field strength on the inner pipe wall. The colour captions on the left top of (a, b) denote the levels of the potential and the electric field strength with blue as the lowest and red as the highest.

3. Analysis of Dynamic sensitivity

Generally, the ring electrode has to be connected to a preamplifier to amplify the induced signal and enhance its loading capability. Thus the frequency characteristics of measurement system are determined by the characteristics of the electrode and the conditioning circuit.

The “dynamic” electrostatic sensors detect the variation of the charge induced on the electrode. Approximately, the function of the conditioning circuit can be expressed as differentiation, i.e. the output voltage of the conditioning circuit is proportional to the rate of change of the induced charge,

$$U_o(t) \propto \frac{dQ(t)}{dt} \quad (12)$$

where $U_o(t)$ is the output of the conditioning circuit, $Q_i$ is the induced charge on the electrode, $\propto$ stands for “proportional to”.

Page 638
It can be seen that, for a given circuit, voltage $U_c(t)$ varies with $\frac{dQ_i}{dt}$, which depends on the location, radial and axial velocities of the moving charged micro-column element. The following derivation is to establish $Q_i$ and $\frac{dQ_i}{dt}$ as the function of the location $(x,r,\varphi)$ where a micro-column element with unity charge travels at the radial velocity $V_r$, axial velocity $V_x$, and produces $Q_i$ and $\frac{dQ_i}{dt}$. Hereafter $Q_i$ is expressed as $Q(x,r,\varphi)$ to indicate that it depends on the location $(x,r,\varphi)$ of the micro-column.

Due to the sensor’s symmetrical axial geometry, the angular position of the charged element does not affect the induced charge on the ring-shaped electrode. Hence $Q(x,r,\varphi)=Q(x,r)$. The simulation can be implemented in the rectangular region as depicted in Fig. 6. The origin $(x=0, r=0)$ is at the geometry center of the sensor.

For given radial positions, e.g. $r=0$ and 80mm for a sensor with the diameter of 14” (355.6mm) and the electrode width of 2mm, the induced charge, $Q(x,r)$ by the micro-column element of one coulomb charge originated from the location $(x=0, r=\text{constant})$ decreases with its axial location $x$ when this micro-column element moves in parallel with the pipe central axis $x$ towards either up or down stream direction. This can be seen in Fig. 7(a). Whilst for a given axial position, e.g. $x=0$ and $x=50$mm, $Q(x,r)$ increases monotonously with $r$, but it decreases with $r$ when the element approaching the edge of the sensing volume shown in Fig. 7(b).

The boundary of the sensing volume in this paper is defined as the edge where $Q_i$ has dropped to the value less than 1% of the maximum, the sensing volume under the above definition is shown in figure 8 where the belt represents the ring probe and the ellipsoidal body is the sensing volume. It is clear though that the sensing volume under this definition is much larger than the geometrical size of electrode along the pipe axis.

The following analytical expression via curve-fitting is derived based on the data contained in Fig. 7(a). From Fig. 9, it can be seen that a double Gaussian model offers high fitting accuracy

$$Q(x,r) = A(r)e^{-B(r)x^2} + C(r)e^{-D(r)x^2} \tag{13}$$

where $A,B,C,D$ are functions of $r$, the radial coordinate of the element for a given electrode.

Fig. 9 illustrates the variation of $Q(x,r)$ with $x$ at $r=80$, the analytical equation at this radial location is for the sensor with the dimensions given above.

$$Q(x,r) \mid_{r=80} = 0.2725e^{-1/3.793x^2} + 0.0953e^{-1/11.63x^2} \tag{14}$$

Figure 10 shows a charged element positioned at $(x,r,\varphi)$ on a circumference and the projections of its velocity vector $V_x$, $V_y$ and $V_z$ on the angular, axial, radial coordinates respectively. When a charged micro-column travels along this circumference, the induced charge on the ring probe won’t change due to the symmetrical configuration of the sensor. Thus the velocity $V_y$ does not contribute to the variation of the total induced charge; only $V_x$ and $V_z$ need to be considered.

Here the dynamic sensitivity $S_{\text{dynamic}}$ is defined as the derivative of induced charge on the probe, when the micro-column carrying unit coulomb of charges, moves at a velocity in the sensing volume:

$$S_{\text{dynamic}} = \frac{dQ_i(x,r,\varphi)}{dt} \tag{15}$$

Substituting $Q_i(x,r,\varphi)$ in Equation (13) with the right side of Equation (15), we have,

$$S_{\text{dynamic}}(x,r,V_x,V_z) = -2x(B(r)A(r)e^{-B(r)x^2} + D(r)C(r)e^{-D(r)x^2}) \cdot V_x + (A(r) \cdot e^{-B(r)x^2}) \cdot V_x + C(r) \cdot e^{-D(r)x^2} - A(r)x^2B(r) \cdot e^{-B(r)x^2} - C(r)x^2D(r) \cdot e^{-D(r)x^2}) \cdot V_x \tag{16}$$

It is clear from equation (16) that the dynamic sensitivity is dependant on the spatial position $(x,r)$, axial velocity $V_x$ and radial velocity $V_r$ of the charged element.

As an example, if this micro-column carrying the unit charge travels along the pipe line at $r=80$mm, the induced charge on the electrode of 355.6mm diameter and 2mm width, i.e. the dynamic sensitivity will be,
\[
S_{\text{dynamic}}(x, r, V_s, V_r) \big|_{r=80\text{mm}, V_y=0} = \frac{dQ(x, r)}{dt} = \left[-0.1437e^{-0.793x^2} - 0.0164e^{-1/11.63x^2}\right] \cdot x \cdot V_s \quad (17)
\]

This is a typical case of equation (16) when ignoring the radial velocity \(V_r\), as shown in Fig.11.

The effect of radial velocity on the sensitivity can be analyzed in the same way. According to the definition of the sensitivity in this paper, the output signal of the conditioning circuit is proportional to \(dQ / dt\) when the charged particle stream passes through the sensing zone at radius \(r\). For simplicity, assume the proportion factor is unity, the output of the conditioning circuit is

\[
\frac{dQ}{dt} = \sum_{(x, r, \varphi) \in \Omega} q(x, r, \varphi) \cdot S_{\text{dynamic}}(x, r, V_s, V_r) \quad (18)
\]

where \(q(x, r, \varphi)\) is the charged local element and \(S_{\text{dynamic}}(x, r, V_s, V_r)\) is the sensitivity, \(\Omega\) denotes the sensing volume.

4. Experiment and analysis

Fig. 12 shows a diagram of the belt rig in the laboratory of the University Teesside, which is used to validate the theoretical analysis discussed above. The rubber belt is pulled by two pulleys, one of which is driven by a DC motor. The speed of DC motor is adjustable to set the belt velocity from 5m/s to 25m/s. A brush is placed at one side to generate electrical charges. The charged belt is used to simulate a stream of charged micro-columns or charged particles traveling along axial direction. The diameter of the sensor is 14” (355.6mm), and the width of the electrode is 2mm. These data are used for numerical simulation in section 3.

Fig. 13 (a) shows the relationship between the belt velocity (\(V\)) and the root mean square value, \(\text{rms}\) of the sensor output at \(r=80\text{mm}\), the vertical coordinate is the normalized value of the output root mean square value. It can be seen that the value of \(\text{rms}\) increases with belt conveyance velocity. Fig. 13 (b) depicts the \(\text{rms}\) versus \(d\) at \(V_x=17\text{m/s}\), the distance of the belt to the pipe wall. It is clear the signal level decreases with \(d\).

5. Discussions

There may be three reasons for the signal increasing with the belt velocity. At first, higher velocity means more intensive friction between the belt and the brush, and between the belt and air, which produces more charges; secondly, even the charge carried by the belt unchanged, the sensitivity increases with axial velocity \(V_x\), it can be seen from Equation (16) and (17); in addition, if the radial movement of the belt represented by \(V_r\) is taken into account, the contribution from it may be more important.

It was observed that the belt vibration was more pronounced in the radial direction with the increased speed of the motor. The standard deviation to mean value ratio of \(\text{rms}\) was significantly higher than at lower velocity. In order to analyze the cause of the signal at the output of the meter under variable belt velocity, we replace the dynamic sensitivity in equation (18) with that in equation (16). It follows,

\[
\frac{dQ}{dt} = \sum_{(x, r, \varphi) \in \Omega} \left[-2q(x, r, \varphi) \cdot x \cdot (B(r)A(r)e^{-B(r\varphi)^2} + D(r)C(r)e^{-D(r\varphi)^2}) \cdot V_s \right. \\
+ q(x, r, \varphi) \cdot (A(r)e^{-B(r\varphi)^2} + C(r)e^{-D(r\varphi)^2} - A(r)x^2B(r)e^{-2(B(r)\varphi)^2} - C(r)x^2D(r)e^{-2(D(r)\varphi)^2}) \cdot V_s \}
\]

It can be seen that \(dQ/dt\) depends on \(q(x, r, \varphi)\) and its distribution, belt velocity in \(x\) and \(r\) directions.

Here presented is an interesting case in which the charges on the belt are assumed to be uniformly distributed over \(-l \leq x \leq l\), where \(-l\) and \(l\) are the boundaries of the sensing volume along a given flow line, from Fig.11, it can be seen that the sum of the terms associated with \(V_s\) in (19) approaches zero. Equation (19) can then be reduced into:

\[
\frac{dQ}{dt} = \sum_{(x, r, \varphi) \in \Omega} q(x, r, \varphi) \cdot (A(r)e^{-B(r\varphi)^2} + C(r)e^{-D(r\varphi)^2} - A(r)x^2B(r)e^{-2(B(r)\varphi)^2} - C(r)x^2D(r)e^{-2(D(r)\varphi)^2}) \cdot V_s \\
= \sum_{(x, r, \varphi) \in \Omega} q(x, r, \varphi) \cdot K(r, x) \cdot V_s
\]

\[
(20)
\]
where \( K(r,x) = A(r) \cdot e^{-B(r)x^2} + C'(r) \cdot e^{-D(r)x^2} - A(r)x^2 B'(r) \cdot e^{-B(r)x^2} - C(r)x^2 D'(r) \cdot e^{-D(r)x^2} \)

which is independent of \( q(x,r,\phi) \) and \( V_r \). In this sense, the output signal of the sensor is related to the radial velocity and the amount of charge carried by the moving belt. The velocity \( V_x \) does not affect the signal.

It cannot be verified in reality if the charges were uniformly distributed along the belt or not. However, for the rig with a belt of uniform property it is reasonable to imagine that there could be more contribution from the radial movement to the sensor’s output than that from the movement along the pipe axis.

In pneumatic conveying system, it has also been observed that at high velocity, the air solids flow is more turbulent, and the signal rms value is higher. This is due to the fact that there is intensified solids radial movement. This may also confirm that the effect of the radial movement of the solids is dominant.

6. Conclusions

In this paper, the 3-D finite element method (FEM) is employed to investigate the dynamic sensitivity of the electrostatic sensor with a ring-shaped probe mounted flush with the inner surface of the pipe wall. Theoretical analyses reveal the dynamic sensitivity depends on the spatial location, the axial and radial velocities of the charged element. From experiments using a belt rig, it confirmed the theoretical analysis regarding the relation between sensitivity and axial velocity as well as the relation between sensitivity and flow stream spatial position. This is the first attempt to identify the effect of the radial velocity on the output signal of the dynamic electrostatic sensor. The test results seem to support the theoretical analysis in this aspect too, although further in depth investigation is required.

\textbf{ABSTRACT}

Product mix problem (PMP) is one of the most important and complicated problems in production systems. Proper determination of product mix leads to high level of profit because it specifies the best way of assigning work centers capacity to each product. In other words, it clears how many of each product should be produced in order to reach a high level of profit. Different approaches have been applied to solve this problem, among them, theory of constraints (TOC) has been widely considered since 1990s. This paper develops a distinguished algorithm to solve product mix problems that is efficient both in single and multi-bottleneck problems. At first, the proposed algorithm uses a mathematical model to aggregate different priorities assigned to products by different bottlenecks and finds an initial solution. Then tries to improve the solution by solving a set of linear inequalities. In this paper, it is discussed that the proposed approach reaches better solutions than the previous algorithms.

1. \textbf{INTRODUCTION}

Theory of constraints (TOC) is a production planning philosophy that was introduced in The Goal [1]. It aims to improve the system throughput by efficient use of bottleneck(s). When there is a bottleneck in the system, the demands of all products cannot be fully met. In this case, the problem is to determine product mix in such a way that high level of profit is obtained. This is called the product mix problem. Although PMP can be formulated as an Integer Linear Programming (ILP) model, it cannot be solved easily in large scale problems. If the number of products increases, the difficulty of solving ILP model will increase exponentially. As a result, many researchers focused on the heuristic algorithms.

Some of the researchers developed algorithms to solve PMP in single bottleneck environment whereas others focused on multi-bottleneck systems. Although many algorithms have been developed to solve PMP in multi-bottleneck systems, most of them fail in reaching desirable solutions. The main reason of their failure is that all decisions are made based on the most capacitated constraint (dominant bottleneck). The common process in the existing algorithms is that the product mix is determined based on priorities of products, i.e. the product with the higher priority is produced first. These priorities are assigned by bottlenecks to products. Each bottleneck assigns a priority (weight) to each product. Most of the previous researches just used the priorities assigned by the dominant bottleneck in determining product mix. Considering only one bottleneck in decision making and ignoring the importance of other ones may distort the solution because only a part of information is used. It is similar to searching for the local optimum instead of the global one.

In this paper, all bottlenecks are considered in product mix decision simultaneously. Each bottleneck assigns a weight to each product. So, there will be \( k \) weight values for each product (\( k \) is the number of bottlenecks). A mathematical model is used to aggregate these values and an aggregated weight is assigned to each product. The initial product mix is obtained using the aggregated weights. Then, the possibility of improving solution is examined through "decrease and increase process". In this process, it is tried to improve the profit by decreasing the

* Corresponding author: Tel.: (98) 912-3242816; Fax: (98) 21-88811727; E-mail: alireza_rashidi@yahoo.com
production amount of one product and increasing the other one. In the proposed algorithm, alternatives to decrease and increase are defined and the best one is selected easily. This causes the speed of solving a problem by the proposed algorithm to be independent from the dimension of the problem. So, the proposed algorithm can be applied in large scale problems properly. In the proposed algorithm, decrease and increase process is done simply by solving a set of linear inequalities. Besides the simplicity of the proposed algorithm, it is shown that it will reach better solution than the existing algorithms. In Sections 3 and 4, the proposed algorithm and its logic are described in details.

2. LITERATURE REVIEW

Solving PMP using TOC heuristic is an interesting area for many researchers. Several algorithms have been developed on this topic since 1990. The first (traditional) algorithm based on TOC was verified by several researchers [2,3]. They showed that the traditional algorithm could lead the optimum solution as ILP.

Balakrishnan and Cheng [4] criticized the traditional algorithm and showed that it could not reach optimum solution in multi-bottleneck systems. Lee and Plenert [5] showed that the algorithm was inefficient in handling problems in which new product alternatives were to be added to an existing production line. Plenert [6] showed by an example that the traditional algorithm was inefficient in utilizing bottleneck resource properly.

Fredendall and Lea [7] revised the traditional algorithm using the concept of dominant bottleneck. The dominant bottleneck is the most capacitated resource. In the revised algorithm, dominant bottleneck assigns a weight (priority) to each product and the initial product mix is developed based on these weight values. Then, the revised algorithm tries to improve the solution using the neighborhood search concept. Fredendall and Lea [7] claimed that the revised algorithm could reach the optimum solution in all cases.

Aryanezhad and Rashidi Komijan [8] discussed several disadvantages of the revised algorithm and showed that it could not reach the optimum solution in all cases and might be stopped in a non-optimum solution. They also showed that the revised algorithm faced burdensome computations when the number of products increases. They discussed that stop condition of the revised algorithm was not defined properly as it might cause the algorithm to reach a non-optimum solution. Then they developed their own algorithm which is called "improved algorithm". It starts with an initial solution and then finds the best path to reach the improved solution with a logical procedure. The ability of improving solution by the improved algorithm is much more than the revised one but however, it is also limited. Tsai and Lai [9] expanded the improved algorithm to systems including joint products.

Hsu and Chung [10] developed an algorithm that was similar to the algebraic concept of simplex to some extent. The main assumption of this algorithm is that the model is continuous not integer. Clearly, there is no need to heuristic algorithms when the problem is considered continuous as simplex can solve large scale problems using advanced softwares like GAMS.

Souren et al. [11] categorized conditions in which TOC heuristic can reach optimum solution and discussed problems that it fails in reaching optimum.

Rashidi Komijan and Sadjadi [12] considered throughput and late delivery cost as decision making criteria and solved PMP problem using TOPSIS technique.

Among other researches, we can mention in [13], [14] and [15]. Kee and Schmidt [13] developed a general model including TOC and Activity-Based Costing (ABC). Bhattacharya and Vasant [14] solved PMP in such a way that decision maker reached higher degree of satisfaction and lesser degree of fuzziness.

3. THE PROPOSED ALGORITHM LOGIC DESCRIPTION

In this section, the logic of the proposed algorithm is discussed in details. In almost all PMP algorithms, the production plan is developed based on priorities of products. These priorities (weights) are determined by the bottlenecks. If there is one bottleneck in the system, there will be a unique weight vector and production plan can be easily obtained. As the resulted product mix is optimal in view of the bottleneck, it is optimal for the whole system. In a multi-bottleneck system, each bottleneck presents its own weight vector and as a result, there may be several weight vectors. The question is that which one of the weight vectors should be considered in developing production plan. Some preliminary algorithms used the weight vector associated to the dominant bottleneck. Naturally the
result may be good in view of that bottleneck not necessarily the others. Considering only one bottleneck in determining product mix and ignoring the importance of other ones is a pitfall for an algorithm.

The proposed algorithm overcomes this problem letting all bottlenecks contribute in determining product mix. In the proposed algorithm, bottlenecks and products are treated as decision-makers (DMs) and alternatives respectively. Using this analogy, the product mix problem is considered as a group decision making problem. Each DM assigns a weight to each alternative (individual weights). Also, as DMs (bottlenecks) do not have equal importance, the weights of DMs are determined in the proposed algorithm. Then, individual weights are aggregated through a mathematical model. The initial production plan is developed using the aggregated weights.

The rest of the algorithm is dedicated to improve the initial plan. This is done using "decrease and increase process". Through this process, the scheduler may decrease the production amount of a product and increase the other one provided that the process leads to a higher profit. Clearly there are too many alternatives for decrease and increase even in a medium scale problem. There are some features in the proposed algorithm that cut the number of alternatives considerably. In the algorithm, it is discussed that the product candidate to decrease should have higher priority that the product considered to increase. On the other hand, as the initial plan is based on the aggregated weights, it has minimum derivation from the desired plan. So the number of alternatives for decrease and increase process is limited and the time consumed in reaching the solution is decreased considerably. Decrease and increase process is applied in [7] and [8] but in the algorithm, it is done in a completely different manner that leads to better solution than the previous algorithms. The proposed algorithm is described in Section 4 and through a numerical example, its result is compared to traditional, revised and improved algorithms. It is shown that the proposed algorithm is more efficient than the previous ones.

4. THE PROPOSED ALGORITHM

The following notations are used in the proposed algorithm:

- $i$: Index of product, $i=1,...,n$.
- $j$: Index of resource, $j=1,...,m$.
- $t_{ij}$: Processing time of product $i$ on resource $j$.
- $D_i$: Demand of product $i$.
- $P_i$: Produced units of product $i$.
- $SP_i$: Selling price of product $i$.
- $RM_i$: Raw material cost of product $i$.
- $CM_i$: Contribution margin of product $i$.
- $AC_j$: Available capacity of resource $j$.
- $RC_j$: Required capacity of resource $j$.
- $PR_{ij}$: Priority of product $i$ assigned by bottleneck $j$.
- $F_{ij}$: Weight of product $i$ assigned by bottleneck $j$.
- $W_i$: Aggregated weight of product $i$.
- $W'_j$: Weight of bottleneck $j$.
- $L_j$: Time left in bottleneck $j$.
- $H_j$: Maximum number of iterations according to bottleneck $j$.
- $H$: Real maximum number of iterations (according to the group of bottlenecks).

Step 1. Identify the system bottleneck(s): Each resource that its required capacity exceeds the available one, is considered as a bottleneck. Required capacity of resource $j$ is calculated as follows:
If $RC_j > AC_j$, then $j$ is a bottleneck.

Step 2. Determine the weight of each product assigned by each bottleneck (individual weights): For each bottleneck, different products have different priorities. Priority of product $i$ in view of bottleneck $j$ is calculated as follows:

$$PR_{ij} = \frac{CM_i}{t_{ij}}$$  \hspace{1cm} (2)

where $CM_i$ is calculated as follows

$$CM_i = SP_i - RM_i$$  \hspace{1cm} (3)

Weight of product $i$ in view of bottleneck $j$ is calculated by normalizing $PR_{ij}$ values:

$$F_{ij} = \frac{PR_{ij}}{\sum_{j=1}^{n} PR_{ij}}$$  \hspace{1cm} (4)

Typically, $(F_{ij} ,..., F_{ij} ,..., F_{ij})$ is the weight vector of products in view of bottleneck $j$. Each bottleneck has a weight vector expressing the weights that it assigns to different products. These weight vectors are called individual weights.

Step 3. Develop production plans regarding the weights obtained in Step 2. In this step, $m$ production plans are developed based on the weights calculated in Step 2. In other words, each bottleneck develops the production plan regarding its own weight vector. Clearly, these plans should be feasible, i.e., the production plan developed by one bottleneck should be feasible for others.

Step 4. Determine the weights of bottlenecks. To determine the weights of bottlenecks, the profit related to each production plan should be calculated. Normalizing these profit values will be led to the weights of bottlenecks.

Step 5. Determine the weight of each product in view of the group of bottlenecks (aggregated weight). In order to calculate the aggregated weight of a product based on the individual weights obtained in Step 2, a mathematical model is formulated as follows:

$$\text{Min } \sum_{j=1}^{m} \sum_{i=1}^{n} W'_{ij} |W_i - F_{ij}|$$  \hspace{1cm} (5)

Subject to:

$$\sum_{i=1}^{n} W_i = 1$$  \hspace{1cm} (6)

$$\min\limits_{j} (F_{ij}) \leq W_i \leq \max\limits_{j} (F_{ij}) \quad i = 1,2,...,n$$  \hspace{1cm} (7)

$$W_i \geq 0$$  \hspace{1cm} (8)
Step 6. Develop production plan regarding the aggregated weights. In this step, the production plan is developed by the group of bottlenecks using the aggregated weights obtained in Step 5. The profit resulted from the aggregated plan may be improved. The improvement will be occurred during a tradeoff, i.e. when the produced amount of one product is decreased and the time left in bottlenecks is dedicated to another product. In the following steps, the possibility of improving the profit is examined.

Step 7. Determine allowable tradeoffs. Decreasing production amount of product $i$ and increasing product $l$ is considered as an allowable tradeoff if $W_i \geq W_l$. In other words, if $W_i < W_l$, decreasing $i$ and increasing $l$ is useless. The reason is simple: In the initial plan, at first we considered $l$ for production and allocated bottlenecks time to it and produced $P_l$ units. If it was possible to produce additional units of $l$, it would be done in the initial plan automatically. Without regarding to the mathematical model, there may be $2!/(n-2)!$ alternatives for decrease and increase process. Using the mathematical model and the condition described in Step 7, the number of alternatives will be cut significantly.

Step 8. Determine how many $l$ should be increased in turn of decreasing one unit of $i$. Assume that $k$ is the number of product $l$ that should be increased in turn of decreasing one unit of $i$. $k$ is the least integer that satisfies the following inequality:

$$k \cdot CM_j \geq CM_i$$  \hspace{1cm} (9)$$

So, in each iteration, it is allowable to decrease one unit of $i$ provided that $k$ units are added to $l$. Now the question is that how many iterations are allowable to be done. This is answered in the following step.

Step 9. Determine the maximum number of iterations. Assuming that decreasing one unit of $i$ and increasing $k$ units to $l$ as one iteration, we want to know that how many iterations are allowable to be done. $L_j$ is the time left in bottleneck $j$ regarding production plan based on aggregated weights and before starting decreasing and increasing process. Decreasing one unit of $i$ causes that $t_{ij}$ minutes are added to the time left in bottleneck $j$ and increasing $k$ units to $l$ consumes $k t_{lj}$ minutes. If $k t_{lj} - t_{ij} \leq 0$, the iterations can be done until production units of $i$ falls to zero or the demand of $l$ is fully met. If $k t_{lj} - t_{ij} > 0$, the iterations can be done until production units of $i$ falls to zero, the demand of $l$ is fully met or bottleneck $j$ exhausts. These can be summarized as follows:

If $k t_{lj} - t_{ij} \leq 0$

Then $$H_j = Min (P_i, \left\lfloor \frac{D_l - P_l}{k} \right\rfloor)$$

Otherwise $$H_j = Min (P_i, \left\lfloor \frac{D_l - P_l}{k} \right\rfloor, \left\lfloor \frac{L_j}{k t_{lj} - t_{ij}} \right\rfloor)$$

where $\left\lfloor \frac{D_l - P_l}{k} \right\rfloor$ and $\left\lfloor \frac{L_j}{k t_{lj} - t_{ij}} \right\rfloor$ are integer values of $\frac{D_l - P_l}{k}$ and $\frac{L_j}{k t_{lj} - t_{ij}}$ respectively.

As the tradeoff must be feasible for all bottlenecks, the above calculation is repeated for all bottlenecks. Each bottleneck suggests a certain number of iteration ($H_j$) and the real maximum number of iterations is the minimum of values suggested by the bottlenecks:

$$H = \min_j H_j$$  \hspace{1cm} (10)$$
Step 10. Calculate net profit change related to the tradeoff between $i$ and $l$. In the previous steps, it was cleared that:

a) It is allowable to decrease $i$ and increase $l$.

b) $k$ units of $l$ should be increased in turn of decreasing one unit of $i$.

c) Part (b) can be repeated for $H$ times.

Clearly, net profit change is calculated as follows:

$$\text{Net Profit Change} = H (k \cdot CM_l - CM_i)$$  \hspace{1cm} (11)

Steps 8 to 10 is repeated for all allowable tradeoffs determined in Step 7. The tradeoff with the highest net profit change is selected.

5. NUMERICAL EXAMPLE

The proposed algorithm is explained through an example. This is the example that was discussed by Hsu and Chung [7]. Assume that a factory produces four products: $R$, $S$, $T$ and $U$. Demand, selling price and raw material cost of the products are shown in Table 1. The contribution margin (CM) is the difference between the selling price and the raw material cost. The factory uses seven resources: A, B, C, D, E, F and G. The processing time of each product in each station is presented in Table 2.

| Table 1. Weekly demand, selling price and raw material cost of each product |
|---|---|---|---|---|
| **Product** | **Demand (Unit)** | **Selling Price ($)** | **Raw Material Cost ($)** | **CM ($)** |
| R | 70 | 100 | 20 | 80 |
| S | 60 | 120 | 60 | 60 |
| T | 50 | 110 | 60 | 50 |
| U | 150 | 50 | 20 | 30 |

| Table 2. Processing time in minute, available and required capacity |
|---|---|---|---|---|---|---|---|
| **Resource** | **Product** | **A** | **B** | **C** | **D** | **E** | **F** | **G** |
| **R** | 20 | 5 | 10 | 0 | 5 | 5 | 20 |
| **S** | 10 | 10 | 5 | 30 | 5 | 5 | 5 |
| **T** | 10 | 5 | 10 | 15 | 20 | 5 | 10 |
| **U** | 5 | 15 | 10 | 5 | 5 | 15 | 0 |
| **Available Capacity** | 2400 | 2400 | 2400 | 2400 | 2400 | 2400 | 2400 |
| **Required Capacity** | 3250 | 3450 | 3000 | 3300 | 2400 | 3150 | 2200 |
| **Difference** | -850 | -1050 | -600 | -900 | 0 | -750 | 200 |

Step 1. According to the last row of Table 2, A, B, C, D and F are bottlenecks.

Step 2. Using contribution margin of each product (the last column of Table 1) and processing times in Table 2, the products priorities in view of each bottleneck are obtained:

| Table 3. Products priorities in view of each bottleneck ($P_{R_i}$) |
|---|---|---|---|
| **Bottleneck A** | 4 | 6 | 5 | 6 |
| **Bottleneck B** | 16 | 6 | 10 | 2 |
| **Bottleneck C** | 8 | 12 | 5 | 3 |
| **Bottleneck D** | 0 | 2 | 3.33 | 6 |
| **Bottleneck F** | 16 | 12 | 10 | 2 |
An Efficient Algorithm Based on TOC to Solve Product Mix Problems

Normalizing each row will lead to the weight vectors:

\[
(F_{RA}, F_{SA}, F_{TA}, F_{UA}) = (0.19, 0.286, 0.238, 0.286)
\]

\[
(F_{RB}, F_{SB}, F_{TB}, F_{UB}) = (0.471, 0.176, 0.294, 0.059)
\]

\[
(F_{RC}, F_{SC}, F_{TC}, F_{UC}) = (0.286, 0.429, 0.179, 0.107)
\]

\[
(F_{RD}, F_{SD}, F_{TD}, F_{UD}) = (0.176, 0.294, 0.53)
\]

\[
(F_{RF}, F_{SF}, F_{TF}, F_{UF}) = (0.4, 0.3, 0.25, 0.05)
\]

Step 3. The production plan is developed based on the above weights as follows:

Production plan in view of bottleneck A: (0R, 60S, 0T, 120U; Profit: 7200)
Production plan in view of bottleneck B: (70R, 50S, 50T, 0U; Profit: 11100)
Production plan in view of bottleneck C: (70R, 60S, 40T, 0U; Profit: 11200)
Production plan in view of bottleneck D: (0R, 0S, 30T, 150U; Profit: 6000)
Production plan in view of bottleneck F: (70R, 60S, 40T, 0U; Profit: 11200)

To illustrate, consider the product mix in view of B. As R is assigned the highest weight by B, it is produced first. After meeting its demand, the next important product, T, is produced. After producing 50 T, the time left in the bottlenecks is only enough to produce 50 S. The profit is calculated by multiplying the produced amount of each product and its contribution margin:

\[
Pr ofit = 70 \times 80 + 50 \times 60 + 50 \times 50 = 11100
\]

Step 4. Weights of the bottlenecks are calculated by normalizing the profit values:

\[
(W_A', W_B', W_C', W_D', W_F') = (0.154, 0.238, 0.24, 0.128, 0.24)
\]

Step 5. The following model is used to determine the weight of each product assigned by the group of bottlenecks (aggregated weight).

\[
\begin{align*}
\min & \quad 0.154|W_R - 0.19| + 0.238|W_R - 0.471| + 0.24|W_R - 0.286| + 0.128|W_R - 0| \\
& + 0.24|W_R - 0.4| + 0.154|W_S - 0.286| + 0.238|W_S - 0.176| + 0.24|W_S - 0.429| \\
& + 0.128|W_S - 0.176| + 0.24|W_S - 0.3| + 0.154|W_T - 0.238| + 0.238|W_T - 0.294| \\
& + 0.24|W_T - 0.179| + 0.128|W_T - 0.294| + 0.24|W_T - 0.25| + 0.24|W_U - 0.286| \\
& + 0.238|W_U - 0.059| + 0.24|W_U - 0.107| + 0.128|W_U - 0.53| + 0.24|W_U - 0.05|
\end{align*}
\]

Subject to:

\[
W_R + W_S + W_T + W_U = 1
\]

\[
0 \leq W_R \leq 0.471
\]
0.176 \leq W_S \leq 0.429

0.179 \leq W_T \leq 0.294

0.05 \leq W_U \leq 0.53

The model is simplified to a linear one:

\[\text{Min } 0.154(W_{RA}^+ + W_{RA}^-) + 0.238(W_{RB}^+ + W_{RB}^-) + 0.24(W_{RC}^+ + W_{RC}^-) + 0.128(W_{RD}^+ + W_{RD}^-) + 0.24(W_{RF}^+ + W_{RF}^-) + 0.154(W_{SA}^+ + W_{SA}^-) + 0.238(W_{SB}^+ + W_{SB}^-) + 0.24(W_{SC}^+ + W_{SC}^-) + 0.128(W_{SD}^+ + W_{SD}^-) + 0.24(W_{SF}^+ + W_{SF}^-) + 0.154(W_{TA}^+ + W_{TA}^-) + 0.238(W_{TB}^+ + W_{TB}^-) + 0.24(W_{TC}^+ + W_{TC}^-) + 0.128(W_{TD}^+ + W_{TD}^-) + 0.24(W_{TF}^+ + W_{TF}^-) + 0.154(W_{UA}^+ + W_{UA}^-) + 0.238(W_{UB}^+ + W_{UB}^-) + 0.24(W_{UC}^+ + W_{UC}^-) + 0.128(W_{UD}^+ + W_{UD}^-) + 0.24(W_{UF}^+ + W_{UF}^-)\]

Subject to:

\[W_{RA}^+ - W_{RA}^- = W_R - 0.19\]
\[W_{RB}^+ - W_{RB}^- = W_R - 0.471\]
\[W_{RC}^+ - W_{RC}^- = W_R - 0.286\]
\[W_{RD}^+ - W_{RD}^- = W_R\]
\[W_{RF}^+ - W_{RF}^- = W_R - 0.4\]
\[W_{SA}^+ - W_{SA}^- = W_S - 0.286\]
\[W_{SB}^+ - W_{SB}^- = W_S - 0.176\]
\[W_{SC}^+ - W_{SC}^- = W_S - 0.429\]
\[W_{SD}^+ - W_{SD}^- = W_S - 0.176\]
\[W_{SF}^+ - W_{SF}^- = W_S - 0.3\]
\[W_{TA}^+ - W_{TA}^- = W_T - 0.238\]
\[W_{TB}^+ - W_{TB}^- = W_T - 0.294\]
\[W_{TC}^+ - W_{TC}^- = W_T - 0.179\]
\[W_{TD}^+ - W_{TD}^- = W_T - 0.294\]
An Efficient Algorithm Based on TOC to Solve Product Mix Problems

\[ W_{TF}^+ - W_{TF}^- = W_F - 0.25 \]
\[ W_{UA}^+ - W_{UA}^- = W_U - 0.286 \]
\[ W_{UB}^+ - W_{UB}^- = W_U - 0.059 \]
\[ W_{UC}^+ - W_{UC}^- = W_U - 0.107 \]
\[ W_{UD}^+ - W_{UD}^- = W_U - 0.53 \]
\[ W_{UF}^+ - W_{UF}^- = W_U - 0.05 \]
\[ W_R + W_S + W_T + W_U = 1 \]
\[ 0 \leq W_R \leq 0.471 \]
\[ 0.176 \leq W_S \leq 0.429 \]
\[ 0.179 \leq W_T \leq 0.294 \]
\[ 0.05 \leq W_U \leq 0.53 \]
\[ W_{ij}^+, W_{ij}^- \geq 0 \]

The optimum solution is:

\((W_R, W_S, W_T, W_U) = (0.343, 0.3, 0.25, 0.107)\)

Step 6. The production plan regarding the aggregated weights is 70R, 60S, 40T and 0U and total profit is 11200 dollars.

Step 7. As the priority of products are R, S, T and U, allowable tradeoffs are shown in Table 4.

<table>
<thead>
<tr>
<th>Decrease from</th>
<th>Increase to</th>
<th>K value</th>
</tr>
</thead>
<tbody>
<tr>
<td>R</td>
<td>S</td>
<td>2</td>
</tr>
<tr>
<td>R</td>
<td>T</td>
<td>2</td>
</tr>
<tr>
<td>R</td>
<td>U</td>
<td>3</td>
</tr>
<tr>
<td>S</td>
<td>T</td>
<td>2</td>
</tr>
<tr>
<td>S</td>
<td>U</td>
<td>3</td>
</tr>
<tr>
<td>T</td>
<td>U</td>
<td>2</td>
</tr>
</tbody>
</table>

Step 8. To illustrate the remaining steps, consider decreasing T and increasing U (the complete calculations are in Table 5). As contribution margins of T and U are 50 and 30 respectively, two units of U should be increased in turn of decreasing one unit of T. So \(k=2\) for this tradeoff.

Step 9. Now the question is that how many times we can decrease one unit of T and increase two units to U. According to the product mix developed in Step 6, the time left in bottlenecks A to F are 0, 1250, 1000, 0, 1550 minutes. Decreasing one unit of T causes that 10, 5, 10, 15 and 5 minutes are added to the time left in bottlenecks and increasing two units to U consumes 10, 30, 20, 10 and 30 minutes. According to bottleneck A, the iterations can be done 40 times:
\[ k_{tUA} - t_{TA} = 2 \times 5 - 10 = 0 \]

\[ H_A = \min(P_T, \left(\frac{D_U - P_U}{k}\right)) = \min(40, \left(\frac{150 - 0}{2}\right)) = 40 \]

Similarly, the following values are calculated:

\[ k_{tUB} - t_{TB} = 2 \times 15 - 5 > 0 \]

\[ H_B = \min(P_T, \left(\frac{D_U - P_U}{k}\right), \left(\frac{L_B}{k_{tUB} - t_{TB}}\right)) = \min(40, \left(\frac{150 - 0}{2}\right), \left(\frac{1250}{2 \times 15 - 5}\right)) = 40 \]

\[ k_{tUC} - t_{TC} = 2 \times 10 - 10 > 0 \]

\[ H_C = \min(P_T, \left(\frac{D_U - P_U}{k}\right), \left(\frac{L_C}{k_{tUC} - t_{TC}}\right)) = \min(40, \left(\frac{150 - 0}{2}\right), \left(\frac{1000}{2 \times 10 - 10}\right)) = 40 \]

\[ k_{tUD} - t_{TD} = 2 \times 5 - 15 < 0 \]

\[ H_D = \min(P_T, \left(\frac{D_U - P_U}{k}\right)) = \min(40, \left(\frac{150 - 0}{2}\right)) = 40 \]

\[ k_{tUF} - t_{TF} = 2 \times 15 - 5 > 0 \]

\[ H_F = \min(P_T, \left(\frac{D_U - P_U}{k}\right), \left(\frac{L_F}{k_{tUF} - t_{TF}}\right)) = \min(40, \left(\frac{150 - 0}{2}\right), \left(\frac{1550}{2 \times 15 - 5}\right)) = 40 \]

\[ H = \min(\{H_A, H_B, H_C, H_D, H_F\}) = 40 \]

\( H \) values for other tradeoffs, that are calculated in a similar way, are zero.

Step 10. Decreasing 40 units from T and increasing 80 units to U will increase the profit value for 400 dollars. As \( H \) values for other tradeoffs are aero, the net profit change according to them are zero. As a result, decreasing T and increasing U is selected and the improved plan is 70R, 60S, 0T and 80U and the profit will be 11600.

Steps 8 to 10 are repeated until no profitable tradeoff is left. The results are summarized in Table 5.

<table>
<thead>
<tr>
<th>Selected Tradeoff</th>
<th>Decrease from</th>
<th>Increase to</th>
<th>K</th>
<th>H</th>
<th>Net change</th>
<th>Product mix</th>
<th>Total profit</th>
</tr>
</thead>
<tbody>
<tr>
<td>T</td>
<td>U</td>
<td>2</td>
<td>40</td>
<td>400</td>
<td>70R, 60S, 0T, 80U</td>
<td>11600</td>
<td></td>
</tr>
<tr>
<td>R</td>
<td>T</td>
<td>2</td>
<td>6</td>
<td>120</td>
<td>64R, 60S, 12T, 80U</td>
<td>11720</td>
<td></td>
</tr>
<tr>
<td>T</td>
<td>U</td>
<td>2</td>
<td>8</td>
<td>80</td>
<td>64R, 60S, 4T, 96U</td>
<td>11800</td>
<td></td>
</tr>
<tr>
<td>R</td>
<td>T</td>
<td>2</td>
<td>2</td>
<td>40</td>
<td>62R, 60S, 8T, 96U</td>
<td>11840</td>
<td></td>
</tr>
</tbody>
</table>

So, the final plan is 62R, 60S, 8T and 96U and the profit is 11840. The result of the proposed algorithm is compared to the traditional, revised and improved algorithms as well as ILP model in Table 6.

6. SUMMERY

A number of algorithms have been developed on determining product mix under TOC. Due to the inefficiency of these algorithms, a new algorithm based on a different and new approach is developed. This paper considers product mix problem as a group decision making problem and benefits from using a linear model to aggregate products weights and finds an initial solution. Then tries to improve the solution based on a new logic for decrease and increase process. Using the linear model ensures that the number of alternatives for decrease and increase is decreased significantly. This helps the algorithm to reach the final solution in a short time. Comparison of the proposed algorithm with the traditional, revised and improved ones shows that the product mix resulted by the proposed algorithm is more desirable than all previous algorithms.

Case Study of Power System Faults in the Petroleum Development Oman (PDO) Network

Wenping Cao*, Nabil Said Al-Kindi
School of Science and Technology
University of Teesside
Middlesbrough, England, TS1 3BA

ABSTRACT

This study is to investigate power system faults in the 33 kV Fahud area under Petroleum Development Oman (PDO) power network. The sequence bus impedance method is used in Matlab environment. The impacts and vulnerability of each bus of interest are investigated so as to find the weakest buses which will need particular attention in power system protection consideration. The main objective is to assess four types of faults as per their levels of fault occurrence and impacts on different buses in the power system so that the behaviour of the power system can be then improved after gathering the correct system information and evaluating results of the faults analysis. Calculation results are confirmed by the practical failures and failure rates.

1. INTRODUCTION

The power system of the Petroleum Development Oman (PDO) is a significant part of electricity supply in Oman, primarily generated from oil and gas. Situated in Fahud and Natih areas, the system consists of 132 kV and 33 kV overhead transmission lines. Each area is supplied from 33 kV switch gears through a transmission line ending to a 33 kV switchyard, then the voltage is stepped down as per the operation requirement.

Fahud sub-system is situated in the northern area under the PDO and is one of the oldest oil fields in Oman. For a while, frequent power faults occur in Fahud area within the PDO power network system, which constantly cause an oil deferment. Among these failure cases, cable termination failures (as shown in Figure 1) occur mostly for 33 kV distribution lines where there is a crossing of graded road. Sometimes these power system failures are due to surge arrestors and 33 kV field isolator damages. When a power failure occurs in this area, an under voltage in the system normally causes a tripping to the circuit breaker, resulting in an escaladed power failure to the location and causing the under voltage relay to activate.

Figure 1: Two cases of cable termination failures of a transmission line within PDO.
(a) Cable insulation failure, (b) Isolator caught flashover.
There are mainly two impacts of the short circuit faults upon the power system, thermal and mechanical effects. Thermal effects on conductors and equipment are created due to heating and excess energy input over time whilst short circuit currents flowing through. Because the short circuit durations are typically short, the heat loss from conductors during the fault may be fairly low. Generally both ac and dc components of the short circuit current contribute to the thermal heating of conductors. Extreme values of the time constant of the dc short circuit current component may be up to 150 ms so that following 500 ms from the instant of the short circuit the dc component is nearly vanished and all its generated heat will have dissipated by around 1s. For the current component, the heat dissipation depends on the ratio of the initial sub-transient rms current to steady state rms current [1].

Power system must be protected against short circuit currents by disconnecting the faulty part of the system via circuit breakers or other breaking apparatus operating in conjunction with protection relays. By doing so, the safe disconnection is guaranteed if the current does not exceed the limit of the circuit breaker. Therefore, the short circuit currents in the network must be analysed beforehand with the precise rating of each appointed system. Short circuit fault calculations should be carried out to ensure the safety of the public as well as the assets. Power system equipment such as circuit breakers are prone to failure with fault duties exceeding their rating. Cables, busbars and transformers are weak thermally or mechanically if subjected to frequent fault currents near their ratings.

2. PDO POWER SYSTEM

The PDO daily requirement for its operation is between 530 MW to around 1400 MW. In 2007, the PDO had about 2400 km of 132 kV overhead transmission lines. There is also an extensive network of 33 kV distribution overhead lines for distributing power to stations, field wells, and utilities. The Fahud sub-system consists of 6 gathering stations and one main pumping station. In addition, there is a booster station which is supplied by the 132 kV transmission line. The power supply in Fahud is transmitted through 33 kV lines across the area. Each feeder is connected to 33 kV switchboards through overhead lines to the located area. Most of the loads in Fahud operate at either 11 kV or 6.6 kV for the large motors and normal 415 volts for the utilities. The Fahud main line pumping station is fed through 33/11 kV while other stations are fed through 33/6.6 kV.

Frequent failures of the power supply in Fahud area have led to costly maintenance and repair. As a result, concerns have been raised about the rationales behind these problems. In economical terms, yearly development is undertaking to improve the oil field production. Compared to other areas of the PDO, there is a significant deferment in Fahud in terms of oil production from the field statistics. This is the main motivation to initiate this project. Though a power fault analysis, short circuit currents at the interested buses in the power system can be computed and compared with the rating of the power system protection equipment such as circuit breakers and relays.

3. SEQUENCE BUS IMPEDANCE METHOD

Analysis of short circuit faults can be conducted using the sequence bus impedance method [2][3]. In an N-bus power system, the system can be modelled by its positive-, negative- and zero-sequence networks where transmission lines and transformers are represented by series reactances, and synchronous machines are represented by constant-voltage sources. If all resistances, shunt admittances, non-rotating loads, and prefault load currents are neglected, the sequence rake equivalents for both symmetrical and unsymmetrical faults at bus n of an N-bus three-phase power system can be obtained. The prefault voltage \(V_i\) is included in the positive-sequence rake equivalent. In this paper, each bus impedance element has an additional subscript 0, 1, or 2 indicating the zero-, positive- and negative-sequence components, respectively.

In order to apply the bus impedance method to the PDO system, a single line diagram for the PDO in Fahud area is produced, as illustrated in Figure 2. In this diagram, the faulty area is simplified to include only 8 buses which have severe fault occurrences in the past and which are of particular interest. Other less significant buses are not numbered in this study so as to reduce the computation effort. This study begins with gathering sufficient data for the existing network which include the buses, bus sequence impedances, and the ratings of transformers and switchgears. The sequence bus impedance method is used in MatLab to evaluate the vulnerability of each bus and the impacts of each faulty bus on any other buses.

Having obtained the strength and weakness of each individual bus, the severity of the power fault strikes can be estimated and ranked in order of significance. The faults considered in this paper consist of balanced 3-phase, single-phase and double-phase fault types. After reviewing the current power system design, some improvements can be
made to protect the weakest buses first. As a result, the overall fault occurrences can be minimised and the system stability be improved.

A simple flow diagram for short circuit calculations is shown in Figure 3. First, all input data are entered and then the sequence and the admittances of each sequence network are identified and labelled in the m file, flowed by converting the admittance matrices into the impedance matrices.
From the theoretical analysis [2], the fault sequence currents for all types of fault at bus $n$ can be computed, as summarised in Table 1. The sequence components of the phase voltages at any bus $k$ during a fault at bus $n$ are found by [3]:

$$ \begin{bmatrix}
V_{k-0} \\
V_{k-1} \\
V_{k-2}
\end{bmatrix} = \begin{bmatrix}
0 & Z_{kn-0} & 0 & 0 \\
V_f & 0 & Z_{kn-1} & 0 \\
0 & 0 & 0 & Z_{kn-2}
\end{bmatrix} \begin{bmatrix}
I_{n-0} \\
I_{n-1} \\
I_{n-2}
\end{bmatrix} = \begin{bmatrix}
-Z_{kn-0}I_{n-0} \\
-V_{kn-1}I_{n-1} \\
-Z_{kn-2}I_{n-2}
\end{bmatrix} $$

Table 1: Fault sequence current calculations
4. RESULTS AND DISCUSSIONS

After obtaining the sufficient bus information, a set of sequence admittance matrices are formed with a matrix size of 8×8. Eight buses are assigned for short circuit fault assessments with a base power of 50 MVA. Using Equations 1-4, the sequence fault currents for the fault bus \( N \) can be computed. As shown in Figure 3, by inverting the three sequence admittance matrices, the corresponding bus impedance matrices can be given (thus the name bus impedance method). Using Equation 5, the bus voltages for all buses can be obtained and so are the phase currents, active and reactive powers. These calculations are complex and therefore conducted in MatLab environment.

4.1 Balanced three phase fault

First, a balanced three phase faults is analysed. The impact of a symmetrical three-phase fault at each bus \( n \) on the eight buses \( k \) are calculated using the sequence bus impedance method. The fault currents and voltages are based on a bolted three phase fault at bus 1 to bus 8. Fault current levels are shown in Figure 4 with the fault bus being 1 to 8 respectively. From Figure 4, it can be seen that the fault current would be significant if the balanced fault occurs at bus 5, 6, 8, 1 in descending order. Clearly this fault represents the most severe type of the faults in the system. However, it does not occur frequently in the PDO system.

![Figure 4: Balanced 3 phase fault current levels.](image)

4.2 Single phase to ground fault
The most frequent type in service is still the single phase to ground fault. Therefore a single phase (phase A) to ground fault is applied and the calculation results from the bus impedance method are given in Table 2.

Table 2: Bus phase voltages during a single-phase-ground fault (pu magnitude/angle)

</table>
From this table, it can be observed that, among all these 8 buses of interest, buses 2, 3, 4, 7 and 8 are likely to be the weakest buses in reducing significance for this type of fault. These buses are found to be problematic in most of the distribution lines. Having checked with the past failure rates, there is a positive correlation between actual failures and these buses identified. In practice, the failures are mostly due to power cable termination failures, lighting arrestors and some types of 33 kV insulators.

4.3 Double phase fault

Phase to phase to ground faults are shown in Figure 5. They are in similar order to the balanced three phase fault.

![Diagram of Fault Buses](image1)

**Figure 5**: Phase to phase fault current magnitudes.

4.4 Double phase to ground fault

Phase to phase to ground faults are shown in Figure 6. They are in similar order to the balanced three phase fault.

![Diagram of Fault Buses](image2)

**Figure 6**: Phase to phase to ground fault current magnitudes.

4.5 Fault power contribution
In terms of fault power contribution, each fault results in different fault power levels. Shown in Figure 7 is a summary of all types of fault with all bus being faulty in turn.

From this figure, the significance of power contributions actually changes with the fault type. If compared to the previous results for fault currents, the buses are not in the similar order of significance. As a result, it may be necessary to consider the different fault current/power levels in protection coordination, taking account of the past history of fault types in the Fahud area.

5. SUMMARY

A case study of the PDO power system has been presented. Short circuit faults are studied including the most severe type (balance three-phase) and the most frequent type (the single to phase to ground). High levels of fault currents and powers can result in thermal and mechanical stresses on the power components and thus cause damage to operational equipment or even to the personnel in the environment.

Using the sequence bus impedance method, the Fahud sub-system is simplified to be an 8-bus single-diagram system for power fault analysis. By computing each individual bus’s impacts on other buses and its vulnerability with reference to a particular type of faults, the significance of the bus can be assessed in terms of its strength and weakness. This information can be used for considering enhancement of existing power system protection. The fault current results on the 8 buses have been confirmed by the actual causes of power failures.

This power fault analysis will lead to a revision of the PDO network and future development plan, based on the past statistics of power system fault and frequency. A further investigation is required using a power flow programme to investigate the Fahud 33 kV power system stability caused by these faults.

ABSTRACT

The complexity of NP-hard optimization problems caused using heuristic solution procedures. The resource-constrained allocation problem (RCAP) in PERT type networks belongs to this class. Therefore, using these procedures is indispensable. Few algorithms are presented in this area in stochastic networks. Most of these algorithms are based on developing and carrying out several strategies to prioritize the activities which must be operated at decision points. In this paper, a new strategy is suggested via traditional strategies in resource management. The three main kinds of strategies were used in literature, have been composed; activity oriented, resource oriented and network oriented. This composed strategy has been used for considered problem, which is the scheduling of project activities subject to finish-start precedence constraints with zero time lag and constant renewable resource constraints in order to minimize the project duration in PERT networks. The new composite strategy performed well, compared to well-known traditional strategies.

1. INTRODUCTION

We will consider a RCAP as follows. A single project consists of a set of activities which have to be processed. The activities are interrelated by two kinds of constraints. First, precedence constraints force each activity not to be started before all its immediate predecessor activities comprised in the set have been finished. Second, performing the activities requires renewable resources with deterministic limited capacities at any decision point, which must be operated prioritize based on strategies. The resource constraints refer to limited renewable resources such as manpower, material and machines which are necessary for carrying out the project activities. Where resources are renewable, activity durations are resource driven [1]. The activity durations are independent continuous random variables; preemption is not allowed. The objective of the problem is the feasible sequence for project activities such that makespan of project be minimized.

Blazewicz et al. [2] have shown that this problem is a generalization of the classical job shop scheduling problem and belongs to the class of NP-hard optimization problems. Therefore, heuristic solution procedures are indispensable when solving large problem instances as they usually appear in practical cases. Since 1963 when Kelley [3] introduced a schedule generation scheme, a large number of different heuristic algorithms have been suggested in the literature [4].

1.1. HEURISTIC IN SCHEDULING

The limited resource project scheduling problem falls into a category of mathematical problems known as combinatorial problems. This is because, for any given problem, a very large number of possible combinations of activity start times exist, with each combination representing a different project schedule. The number of

* Corresponding author: Tel.: (+9821) 66413034; Fax: (+9821) 66413025; E-mail: fatemi@aut.ac.ir
combinations is extremely large, and increases rapidly with an increase in the number of activities. In fact, the number is typically so large for realistic-sized problems as to prohibit enumeration of all alternatives, even with the aid of a computer. Analytical methods such as mathematical programming have not proven very successful on these combinatorial problems. Instead, various heuristic-based procedures have been developed [5]. Heuristics may not always produce the best solution in every case, but their usefulness in finding good solutions with a minimum of effort is well-known, based on experience and research studies. The heuristic procedures broadly fall into two categories, namely constructive heuristics and improvement heuristics [6]. Constructive heuristics consist of two major components, namely the scheduling scheme and the priority rule. The scheduling scheme determines the way in which a feasible schedule is constructed by assigning starting times to the different activities. The priority rule determines the activity that is selected next during the heuristic search process.

Many researchers have investigated the resource allocation problem; Brucker et al. [7] and Ozdamar and Ulusoy [8] present extensive overviews of resource allocation research. Strategies and priority rules can be classified in three kinds of strategies are used in literature [9]. The first group is the activity oriented (base) priority rules which consider information related to the activity; the second is the resource oriented (base) priority rules which consider the resource use of the different activities. The third is the network oriented (base) priority rules which only consider the information contained in the network itself, not to the rest of the project.

The three main kinds of strategies were used in literature, have been composed and applied this composed strategy for considered problem. The new composite strategy compared to well-known traditional strategies. According to the classification scheme for project scheduling from Herroelen et al. [10], a regular performance measure is used, in particular the makespan. That is to say, the objective is to minimize the project makespan. Instead of analyzing the merely makespan values, the percentage increase in the makespan values with respect to the best possible solution project duration has been analyzed. Thus, this is a measurement of the efficiency, given that the performance of the new combination has been compared with the best possible solution.

The paper is organized as follows. Section 2 deals with the problem description. Section 3 gives the development of new strategy for RCAP in PERT networks “RAP”. Experimental design is treated in Section 4. Section 5 is devoted to the discussion and the paper has been ended with the conclusions in Section 6.

2. THE PROBLEM FORMULATION

The well-known resource-constrained allocation problem (RCAP) can be stated as follows:

Project network G(N, A) is shown as PERT type network with an activity-on-arc (AOA) format, the set of arcs A are used to represent the n activities (numbered from 1 to n, i.e.) and a set of nodes N represent the precedence relations between activities, which are assumed to be finish-start relations with a minimal time-lag of zero. Activity durations are independent continuous random with given distribution function which requires only renewable resource. The amount of limited available resource is deterministic and allocated is performed discretely. The activities are assumed to be nonpreemptable. A regular performance measure is used, in particular the makespan. That is to say, the objective is to minimize the project makespan.

According to above, the considered model is defined as follows:

\[
\begin{align*}
G(N,A) & \quad \text{stochastic network (graph) of PERT type with A activities and N as the set of precedence relationships} \\
(i, j) \in A & \quad \text{the project’s activity } (i, j) \\
F_i & \quad \text{the finish time of activity } (i, j) \\
R_k\left(t / F_i\right) & \quad \text{maximal value of the } k \text{-th resource profile at point of } t \text{ on condition that activities } (i, j) \in A \text{ are finished at point of } t \\
T(G) & \quad \text{random variable of project completion time} \\
R_k & \quad \text{total available resource of type } k \text{ at the project management disposal (pre-given and fixed throughout the planning horizon)} \\
K & \quad \text{number of different resources} \\
SAS & \quad \text{scheduled activity set}
\end{align*}
\]
According to the notations, the considered model is defined as follows:

\[
\text{Min}_{ij} f( E(T(G)/ F_{ij}) ) \\
\text{s.t.: } R_k^e(t/F_{ij}) \leq R_k, \\
\quad 1 \leq k \leq K \quad \forall t \geq 0.
\] (1)

The problem is to determine the values of \( F_{ij} \) in order to minimize makespan of project. The set of constraints in this model shows that at each decision point \( t \), the maximum required amount of resource \( k \) is equal or less than its available amount. Model (1) is a stochastic optimization model which cannot be solved in the general case due to its intractability; hence, only a heuristic solution can be applied.

3. THE DEVELOPMENT OF NEW STRATEGY FOR RCAP IN PERT NETWORKS

It seems the strategies are needed for activity selection at decision points. Each priority rule has a characteristics and predictable behavior. Obviously when the priority rules are combined together, the behavior would be changed and new behavior depends on what kind of combination has been made. The strategy can be applied with simple or combination form.

In simple form priority rules may be used in the single or sequential form. In sequential form some priority rules are used as sequential at several steps. For combination of rules, two kinds of operators can be employed. They are summation operator and multiplication operator. When kinds of priority rules are combined with summation operator, each priority rule can be used in simple or weighted form. For combination with multiplication operator, each priority rule can be used in normal or reverse form.

The main purpose of this paper is to use synergy of rules combination. There are kinds of composite rules that their efficiency must be evaluated to select the best possible solution. As mentioned previously, according to the literature [9] the priority rules can be classified in three major groups, activity oriented, resource oriented and network oriented. It can be considered Resource Criticality Index (\( RCI \)), Activity Time Density (\( ATD \)) and Path Index (\( PI \)), respectively as representative of the mentioned groups. Resource Criticality Index (\( RCI \)) is denoted by \( \text{Max}_{ij \in SAS} (R_{ij} \text{activity resource requirement}) / \text{Total resource availabilities} \) and calculated by the following relation:

\[
RCI = \frac{\text{Activity resource requirement}}{\text{Total resource availabilities}}
\] (2)

Activity Time Density (\( ATD \)) is denoted by \( \text{Max}_{ij \in SAS} (ATD_{ij}) \) and calculated by the following relation:

\[
\text{ATD} = \frac{\text{Activity duration}}{\text{Activity duration} + \text{Activity slack}}
\] (3)

It is important to say in this paper stochastic networks are considered with activity continuous time. Therefore generalization of dynamic index has been needed like Activity Time Density (\( ATD \)). To calculate \( ATD \), it is required to calculate the activity duration and the activity slack. However the durations and slacks of activities in PERT type networks are random variables. Their average has been applied estimated by simulation. This rule is noted by \( \text{Max} \ ATD \). Indeed the activities duration times have been generated randomly and simulated the network \( M \) times and computed \( ATD \) with following relation:

\[
\overline{ATD}_q = (\sum_{ij \in A} ATD^q_{ij}) / M \quad (i, j) \in A \quad \text{and} \quad q = 1,2,...,M
\] (4)

Activity Path Index (\( PI \)) is noted by \( \text{Max}_{ij \in SAS} (PI_{ij}) \) and is the number of paths which pass from activity.

As mentioned previously, activities in PERT type networks is random variable. Their average has been applied estimated by simulation. Based on above conclusion the network makespan has been computed by simulation. The
mean of makespan has been computed for all of problems through applying each rule in each type of networks denoted by $\overline{MKSP}$.

$$\overline{MKSP}_q = \left( \sum_{i,j}^n \text{Makespan}^q_{ij} \right) / M \quad (i, j) \in A \quad \text{and} \quad q = 1, 2, \ldots, M$$ (5)

The new strategy is constructed with the combination of three rules; Resource Criticality Index (RCI), Activity Time Density (ATD) and Path Index (PI) that is called “RAP”. The performance of the new strategy is investigated by designing experiments and evaluation of each combination of schemes.

4. EXPERIMENTAL DESIGN

The RAP has been analyzed with respect to the solutions obtained with the best heuristic method in literature. The evaluation method is based on the design of experiments.

4.1. FOUR TYPES OF NETWORK STRUCTURE

The experience gained in resource-constrained allocation with heuristic and optimization procedures has clearly shown that the effectiveness of both types of procedures is strongly dependent upon the characteristics of the particular problem being solved. It has been attempted to have different configurations for network structure considered in the evaluating the alternatives. Having attention to reference Kurtulus and Davis [11], four different types of structures have been considered for networks of this paper. Figure 1 illustrates these structures.

In type A the number of parallel activities is more in the initial portion of network and less in the final portion (Figure 1.a) while in type B it is less in the initial portion of network and more in the final portion (Figure 1.b). For type C the numbers of parallel and independent paths are high in the network (Figure 1.c) and type D the number of parallel activities, in the initial or final portion of network does not make so much difference. The paths are not independent of each other and have common activities (Figure 1.d).

**Figure 1: Four types of network structure**

4.2. EXPERIMENTAL DESIGN

Each activity has the same duration and the same renewable resource requirements in different network types. A designed experiment was used to determine the effect of final three forms of how to apply priority rules in network types. In all cases, four replicates of each treatment combination were made. Therefore (4 different types of A, B, C and D) × [(3 single form) + (6 sequential form) + (7 summation operator) + (7 multiplication operator)] = 92 problems were constructed and solved. The activities durations of the test networks have been randomly generated with Uniform distribution function. To solve all 92 problems, they were coded in Visual Basic 6.0.

The combination schemes have been evaluated for the two specific cases. The performance of the new composite strategy was investigated by comparing solutions of the different combination schemes in two specific cases. Indeed
the results are compared with the other solutions especially with well-known traditional strategy, the Time Criticality Index \( (TCI) \) which is denoted by \( \text{MaxTCI} \) and calculated by the following relation:

\[
TCI = \frac{\text{No. of criticality status for each activity}}{M} \times 100
\]  

where \( M \) is the number of simulation runs.

The number of criticality status has been applied for each activity in simulation runs and calculated the percentage of criticality. Indeed the activities duration times have been generated randomly and simulated the network \( M \) times and computed \( TCI \). In the first case, combination schemes of \( \text{RAP} \) efficiency is measured against the best possible solution (BPS) that is the minimum of \( \text{MKSP} \) for each network type. As mentioned previously, in this case the best possible solution is selected and compared with the other solutions especially with the Time Criticality Index \( (TCI) \) solution. Therefore, by resolving the resource conflicts with the \( \text{MaxTCI} \) in comparison to the best possible solution the validation of our index is approved, which is expressed in percentage denoted by “Index of Best Possible Solution” (IBPS) as follows:

\[
\text{IBSP} = \frac{\text{MKSP} - \text{Best Possible Solution}}{\text{Best Possible Solution}} \times 100
\]

Also the efficiency of the single project environment in larger projects can be measured with regard to critical path \[12\]. Therefore in the second case efficiency of new combined priority rule \( \text{RAP} \) is measured against mean of “Initial Critical Path” which is mean of makespan by \( M \) times network simulation with non-constraint resources. Therefore it is expressed in percentage the difference of makespan in two situations and denoted by “Index of Critical Path” (ICP) as follows:

\[
\text{ICP} = \frac{\text{MKSP} - \text{Initial Critical Path}}{\text{Initial Critical Path}} \times 100
\]

Additionally in this case the initial critical path solution has been compared with other solutions and especially with the \( \text{MaxTCI} \) solution in single form of priority rules. Thus, by resolving the resource conflicts with the \( \text{MaxTCI} \) in comparison to other solutions the validation of our selected index is approved. The two mentioned cases allow us to correctly evaluate efficiency of \( \text{RAP} \).

5. DISCUSSION

The \( \text{RAP} \) has been analyzed with respect to the solutions obtained with one of the best heuristic method in literature. As mentioned, four different types of A, B, C and D have been considered for experiments. The first results are shown in Figure. 2 which illustrates the mean of makespan (\( \text{MKSP} \)) values to compare efficiency of \( \text{RAP} \) forms for all selected networks. The experiments and analysis are divided into two cases to compare efficiency of the schedules when the project resources have limited availabilities. The first case is formed by the best possible solution and the second case is formed by initial critical path. Table 1 contains the values of networks solutions to evaluate the \( \text{RAP} \) in resource-constrained project scheduling. In the following section the results have been explained and analyzed \( \text{RAP} \) efficiency by behavior networks analysis and behavior indices analysis in details.

As mentioned previously, the main purpose of this paper is to use synergy of rules combination. Special attention should be made of the interactions between networks types with \( \text{MaxTCI} \), which showed a new light on the previous results. Although according to the literature \( \text{MaxTCI} \) is well-known and one of the best priority rules, in single form its efficiency is not higher than combined rules. As Figure.3 demonstrates, it has the rank of twentieth for network type A, third for network type B, fourteenth for network type C and twenty third for network type D. In none of four network types it gained the first rank.

Figure. 3 illustrates and compares efficiency of \( \text{MaxTCI} \) against the other considered rules in four networks types. This figure shows in type A, 83.33% solutions are better than \( \text{MaxTCI} \), and in type B this percent is 8.33%.
While there are 54.16% and 91.66% for types C and D. These percents refer to high efficiency of MaxTCI in type B and low efficiency in type D. All of these results illustrate the synergy of rules combination. Indeed results confirm that combinations of heuristics can be used to find better solutions to resource allocation problems than single heuristics. As the results indicate, for type A, 78.26% indices have been found the best possible solution.

![Network makespan in different indices](image)

**Figure 2:** Behaviors of mean of makespan (MKSP) in four networks types

These are 8.70% in single form, 26.09% in sequential form, 30.43% in summation form and 13.04% in multiplication form with project makespan 44.89. In type B there is 8.70%. They are 4.35% in summation form and 4.35% in multiplication form with project makespan 47. For type C there are 4.35% in single form, 13.04% in sequential form, 17.39% in summation form and 8.70% for multiplication form with project makespan 48.89. In type D there are 4.35% for single form, 8.70% in sequential form and 30.43% for summation form and 4.35% for multiplication form with project makespan 44.85.

![Difference among MaxTCI and other indices in four networks types](image)

**Figure 3:** Difference among MaxTCI and other indices in four networks types

Regarding the interaction RAP by four networks, as mentioned, the analysis is performed for two cases for comparison of the schedules when the project resources have limited availabilities. The first case is formed by the best possible solution, which presents a high performance and the second case is formed by critical path. Table 1 shows the percent differences among the values (MKSP) with the best possible solution (minimum of MKSP) and initial critical path (ICP). Table 1 gives the differences clearly. The interpretation is that comparing the MKSP with index of critical path (ICP), in type A, there are 49.58% difference between the best possible solution and initial critical path, and 92.77% difference between the worst solution and initial critical path. It means that there are range values around 43.19 differences. In type B there is a range percent difference between the best possible solution (94.54%) and worst solution (110.64 %) about 16.10 % difference. For type C there is the range between 69.87% and 87.63% that indicates around 17.76 % difference. Finally there is 25.89 % difference between the best possible solution (45.15%) and the worst solution (71.04%) in type D. With respect to the above
results it appears that the differences between the network types of B and C are similar and network type D is almost similar to both of them; while results of network type A is different with others. Regarding the best possible solution (IBPS) and index of critical path (ICP) percents, it can be said that the network structure plays an important role in efficiency of each index.

</table>

The performance of $RAP^{+/-}$ appears in Table 1. The results of $RAP^{+/-}$ are also surprising. As Figure. 4 clearly displays, this index is the best possible solution for all of the four different network types of A, B, C and D considered for design of experiments. Indeed it is common and distinct solution for all of four networks types. $RAP^{+/-}$ Presents the most efficient solution with reference to resource constrained project scheduling. However because of problem complexity, its quality of solutions compared with the optimal solutions is unknown.

Figure 4: Comparing the RAP$^{+/-}$ with other indices in four networks types
6. CONCLUSIONS

The main objective of this paper was to develop a new combined priority rule as a computationally simple method to find good solutions to resource constraint allocation problems (RCAP). The new combined priority rule, developed for stochastic problems, was adapted to the resource allocation problem with activity continuous distribution function and demonstrated on an established test set of resource allocation problems. The new combined priority rule performed well compared to other well-known heuristics like MaxTCI, that according to the literature it is one of the best well-known priority rules. In investigation of 92 problems, the experiments show that, RAP was able to find the best possible solution for all of four types of networks.

Our evaluation has demonstrated that the area in which there are higher differences regarding capabilities and efficiency of the indices for resource-constrained project scheduling, a new combined priority rule (RAP) could be constructed with combination of three rules; Resource Criticality Index (RCI), Activity Time Density (ATD) and Path Index (PI), that its efficiency is superior than each rule. The experiments confirmed the synergy of rules combination and illustrated that combinations of heuristics can be used to find better solutions to resource allocation problems than single heuristics. Some indices only allow the consideration of simple networks, while others also include complex networks. Finally, regarding the criteria for resource allocation to different activities in the resolution of the mentioned problems RAP is more appropriate than other indices in this sense.

To correctly evaluate the efficiency of the schedules obtained with the different indices two designs of experiments have been created, one in the scheduling of constrained resources in single projects with the best possible solution and the other with index of critical path (ICP). In both designs, instances have been generated in which all the relevant project characteristics have been experimented. The results point out the significant differences in performance of the different indices. Thus, RAP was the most efficient because it offers the schedules with the shortest duration, even better than the other indices, such as single form, multiplication form and summation form. It is also remarkably to note that the most efficient indices have a better performance than the classical methods such as MaxTCI.

FUZZY ELECTRE: A Multi-Attribute Method In Fuzzy Environment

S.M.T. Fatemi Ghomi*, Mehdi Iranpoor, R. Ghasemy Yaghin

Department of Industrial Engineering, Amirkabir University of Technology, Hafez Ave. No. 424, 15916-34311 Tehran, Iran

ABSTRACT

Decision makers often deal with situations, which include incomplete information as vagueness. On the other hand, most of the real-world problems have more than one attribute to be evaluated. Electre is one of the multi-attribute decision making (MADM) methods, which concentrates on the dominance relations among the alternatives. In this paper, we develop Fuzzy Electre method as a multi-attribute decision making approach in fuzzy environment. We suppose that both the rating of options and the weights of criteria are trapezoid fuzzy numbers.

1. INTRODUCTION

In recent years, multi-criteria decision making (MCDM) problems have been widely discussed by researchers.

In real-world situations, because of incomplete or non-obtainable information -for example human judgments including preferences are often vague and he cannot estimate his preference with exact numbers- therefore they usually are fuzzy/imprecise or interval numbers. Fuzzy set theory was first used to solve decision-making problems by Bellman and Zadeh [1]. Laarhoven and Pedrycz extended Saaty's AHP to deal with the imprecision and subjectiveness in the pairwise comparison process [2]. Jahanshahloo et al. extended the concept of TOPSIS to develop a methodology for solving multi-criteria decision-making problems with interval data [3]. Chen further extended the concept of TOPSIS to develop a methodology for solving multi-person multi-criteria decision-making problems in fuzzy environment [4]. Considering the fuzziness in the decision data and group decision-making process, Chen used linguistic variables to assess the weights of all criteria and the ratings of each alternative with respect to each criterion. Aouam et al. introduced a new methodology that combines both the concept of fuzzy outranking and fuzzy attributes to provide a more flexible way for comparing alternatives [5]. Lee built a group decision-making structure model of risk in software development and proposed two algorithms to tackle the rate of aggregative risk in a fuzzy environment by fuzzy sets theory during any phase of the life cycle [6]. Hsu and Chen proposed a method for aggregating individual fuzzy opinions into a group fuzzy consensus opinion [7]. They presented a procedure for aggregating the expert opinions. Herrera et al. presented a consensus model in group decision-making under linguistic assessments [8]. It is based on the use of linguistic preferences to provide individuals’ opinions, and on the use of fuzzy majority of consensus, represented by means of a linguistic quantifier. Li investigated the problems of decision-making with multiple judge, multiple criteria in a fuzzy environment, where the performance of alternatives and the importance of criteria are imprecisely defined and represented by fuzzy sets [9]. A fuzzy model associated with the solution algorithm is proposed on the basis of an $\alpha$-level weighted, fuzzy preference relation.

Electre is one of the other MADM methods, which concentrates the analysis on the dominance relations among the alternatives. That is, this method is based on the study of outranking relations, exploiting notions of concordance. These outranking relations are built in such a way that it is possible to compare alternatives. The information required by Electre consists of information among the criteria and information within each criterion. It is a comprehensive evaluation approach in that it also tries to rank a number of alternatives each one of which is described in terms of a number of criteria. The main idea is the proper utilization of what is called “outranking

* - Corresponding author: Tel.: (009821)66413034 Fax: (009821)66413025; E-mail: fatemi@aut.ac.ir
relations”. Electre is more than just a solution method; it is a philosophy of decision aid. This philosophy is discussed at length by Roy [10]. Electre has evolved through a number of versions (I through IV); all are based on the same fundamental concepts but are operationally somewhat different.

Some of the situations in which Electre methods are more suitable than aggregation methods, are listed below [11].

1. The decision-maker (DM) wants to include in the model at least three criteria. However, aggregation procedures are more adapted in situations when decision models include more than five criteria (up to twelve or thirteen).

2. A strong heterogeneity related with the nature of evaluations exists among criteria (e.g., duration, noise, distance, security, cultural sites, monuments, ...). This makes it difficult to aggregate all the criteria in a unique and common scale.

3. Compensation of the loss on a given criterion by a gain on another one may not be acceptable for the DM. Therefore, such situations require the use of noncompensatory aggregation procedures (e.g. Electre methods).

4. For at least one criterion the following holds true: small differences of evaluations are not significant in terms of preferences, while the accumulation of several small differences may become significant. This requires the introduction of discrimination thresholds (indifference and preference) which leads to a preference structure with a comprehensive intransitive indifference binary relation.

In this paper, we introduce fuzzy Electre method. We suppose that the weights of attributes and the rates of options with respect to attributes are trapezoid fuzzy numbers.

In Section 2, we introduce the problem and notations. Section 3 and 4 develops Fuzzy Electre method. In Section 5, a numerical example is presented. Finally, Section 6 is devoted to the concluding remarks.

2. Problem Description and Notations

Electre is one of the multi-criteria decision making methods. This method concentrates on outranking relations between alternatives to find a subset of partially dominant alternatives. In this paper, we develop this method in a fuzzy situation which both weights of the criteria and ratings of the alternatives are expressed in trapezoid fuzzy numbers.

The parameters of this problem are as follows:

\( A_j \): Attribute \( j \)

\( O_i \): Option (alternative) \( i \)

\( n \): Number of attributes

\( m \): Number of options

\( w_j \): Weight of attribute \( j \)

\( c_{ke} \): Degree of concordance of relation “alternative \( k \) is at least as good as alternative \( e \)”

\( d_{ke} \): Degree of discordance of relation “alternative \( k \) is at least as good as alternative \( e \)”

To be more familiar with the definition of \( c_{ke} \) and \( d_{ke} \), note that:

\( c_{ke} \) informs us about the strength of preference for the alternative \( k \), with respect to the alternative \( e \) when considering all the criteria, while,

\( d_{ke} \) informs us about the evidences \textit{against} the preference of alternative \( k \) with respect to alternative \( e \) under the consideration of all of the criteria.

3. Fuzzy Electre Method

Suppose that the decision matrix is as follows:
\[
\begin{bmatrix}
A_1 & A_2 & \cdots & A_j & \cdots & A_n \\
O_1 & & & & & \\
O_2 & & & & & \\
\vdots & & & & & \\
O_t & & \cdots & \tilde{x}_{ij} & & \\
\vdots & & & & & \\
O_m & & & & & \\
\end{bmatrix}
\]

In this problem, both \( \tilde{x}_{ij} \) s and the weights of the attributes are trapezoid fuzzy numbers. So, we have:

\[
\tilde{x}_{ij} = (a_{ij}, b_{ij}, c_{ij}, d_{ij}) 
\]

\[
\tilde{\omega}_j = (\alpha_j, \beta_j, \gamma_j, \delta_j) 
\]

We suppose that all the fuzzy numbers are positive. In other words, for each trapezoid fuzzy number \( \tilde{\nu} = (\nu_1, \nu_2, \nu_3, \nu_4) \), we have:

\[
\nu_4 \geq \nu_3 \geq \nu_2 \geq \nu_1 \geq 0
\]

The fuzzy Electre method includes the following steps:

Step1. Smooth the range of fuzzy elements in every attribute using the following expression:

\[
\tilde{r}_{ij} = \begin{cases} 
\frac{a_{ij} + b_{ij} + c_{ij} + d_{ij}}{4d_j} & \text{for the positive attributes} \\
\frac{-a_{ij} - b_{ij} - c_{ij} - d_{ij}}{4d_j} & \text{for the negative attributes}
\end{cases}
\]

where;

\[
d_j^* = \max_i \{d_{ij}\}
\]

In expression 3, positive attributes are the attributes which the decision maker wants to maximize them (profit-like attributes), while negative attributes are the attributes which the decision maker tries to minimize them (cost-like attributes).

So, the smoothed decision matrix, which is called normalized decision matrix, would be as follows:

\[
R = \begin{bmatrix}
\tilde{r}_{11} & \tilde{r}_{12} & \cdots & \tilde{r}_{1n} \\
\tilde{r}_{21} & \tilde{r}_{22} & \cdots & \tilde{r}_{2n} \\
\vdots & \vdots & \ddots & \vdots \\
\tilde{r}_{m1} & \tilde{r}_{m2} & \cdots & \tilde{r}_{mn}
\end{bmatrix}
\]

Step2. Multiply each column of matrix R by the weight of its corresponding attribute.
\[ \tilde{v}_j = \tilde{r}_j \otimes \tilde{w}_j = (a_y \alpha_j, b_y \beta_j, c_y \gamma_j, d_y \delta_j) \] (5)

where, \( \tilde{r}_y = (a_y, b_y, c_y, d_y) \) and \( \tilde{w}_j = (\alpha_j, \beta_j, \gamma_j, \delta_j) \) are the elements of matrix \( R \) and the weights of attributes, respectively.

Step3. For each pair of options \( e \) and \( k \), compose the following sets:

\[ C_{ke} = \{ j \mid \tilde{v}_{kj} \geq \tilde{v}_{ej} \} \] (6)
\[ D_{ke} = \{ j \mid \tilde{v}_{kj} < \tilde{v}_{ej} \} \] (7)

Note that, for comparing two fuzzy numbers \( \tilde{x} \) and \( \tilde{y} \), we have:

\[ \text{IF} \{ M(\tilde{x}) > M(\tilde{y}) \ \text{OR} \ \{ M(\tilde{x}) = M(\tilde{y}) \ \text{AND} \ \sigma^-(\tilde{x}) < \sigma^-(\tilde{y}) \} \} \]
\[ \text{THEN} \ \tilde{x} \succ \tilde{y} \]

where, \( M(\tilde{x}) \) is the mean of \( \tilde{x} \) and \( \sigma^-(\tilde{x}) \) is its negative standard deviation. Especially, for a trapezoid fuzzy number \( \tilde{x} \), we have:

\[
\begin{align*}
\text{Degree of possibility} \\
\begin{array}{c}
\text{Value of } x \\
\hline
a & b & c & d
\end{array}
\end{align*}
\]

Figure 1: A trapezoid fuzzy number

\[
M(\tilde{x}) = \frac{c^2 + 3d^2 + cd - a^2 - b^2 - ab}{3(c + d - a - b)}
\] (9)

and;

\[
\sigma^-(\tilde{x}) = \sqrt{E[(x - M)^2]}
\] (10)

where;

\[
(x - M) = \begin{cases} 
 x - M & : x \leq M \\
 0 & : x > M 
\end{cases}
\] (11)

By substituting \( M(\tilde{x}) \) in (10), we have:

\[
\sigma^-(\tilde{x}) = \sqrt{ \int_a^b \left[ \frac{x - M}{b - a} (x - M)^2 \right] dx + \int_b^d \left[ (x - M)^2 \right] dx }
\] (12)

\[
= \left[ \frac{1}{2} \left( \frac{b^4}{4} - (2M + a) \frac{b^3}{3} + (M^2 + 2Ma) \frac{b^2}{2} - \frac{a^4}{4} \right) \\
+ (2M + a) \left( \frac{a^3}{3} - (M^2 + 2Ma) \frac{a^2}{2} + M^3 - Mb^2 + Mb^2 - \frac{b^3}{3} \right) \right] ^{\frac{1}{2}}
\]

Step4. Compose concordance matrix \( C \) and discordance matrix \( D \) for all of the relations “alternative \( k \) is at least as good as alternative \( e \)” as follows:
\[
c_{k\epsilon} = \frac{\sum_{j=1}^{n} M(\tilde{v}_{ij})}{\sum_{j=1}^{n} M(\tilde{v}_{ij})} \quad (13)
\]

and;

\[
d_{k\epsilon} = \frac{\max_{j \in D_{k\epsilon}} [M(\tilde{v}_{ij}) - M(\tilde{v}_{ij})]}{\max_{j=1,n} [M(\tilde{v}_{ij}) - M(\tilde{v}_{ij})]} \quad (14)
\]

where, \( M(.) \) is the mean function of fuzzy number.

Step 5. Compose the final dominance matrix \( (F) \) as follows:

5.1) Let

\[
\bar{c} = \sum_{k=1}^{m} \sum_{\epsilon=1}^{m} \frac{c_{k\epsilon}}{m(m-1)}
\]

5.2) Let

\[
\bar{d} = \sum_{k=1}^{m} \sum_{\epsilon=1}^{m} \frac{d_{k\epsilon}}{m(m-1)}
\]

5.3) The final dominance matrix would be as follows:

\[
f_{i\epsilon} = \begin{cases} 
1 & : c_{i\epsilon} \geq \bar{c} \text{ and } d_{i\epsilon} \leq \bar{d} \\
0 & : \text{Otherwise}
\end{cases}
\]

Step 6. Eliminate options which are significantly dominated.

Unfortunately in step 6, except the completely dominated options, identifying that which other options can be dominated is somehow vague. To solve this problem, one way is using the following measures:

\[
c_{k} = \sum_{\epsilon=1}^{m} c_{k\epsilon} - \sum_{\epsilon=1}^{m} c_{\epsilon k} \quad (18)
\]

\[
d_{k} = \sum_{\epsilon=1}^{m} d_{k\epsilon} - \sum_{\epsilon=1}^{m} d_{\epsilon k} \quad (19)
\]

where, options (alternatives) which have larger \( c_{k} \) and smaller \( d_{k} \) are more preferable.

4. Numerical Example

Suppose that the initial decision matrix and the weights of the attributes are as follows:
\[ \vec{w}_1 = (1, 2, 3, 4); \vec{w}_2 = (2, 5, 6, 8); \vec{w}_3 = (3, 4, 6, 7) \]

Furthermore, suppose that the second attribute is negative.

Solution:

The weighted normalized decision matrix would be as follows:

\[
V = \begin{bmatrix}
(0.11, 0.33, 0.55, 0.89) & (-1.00, -0.89, -0.78, -0.22) & (0.25, 0.37, 0.50, 0.62) \\
(0.11, 0.55, 0.78, 0.89) & (-0.89, -0.78, -0.67, -0.55) & (0.25, 0.75, 0.87, 1.00) \\
(0.55, 0.78, 0.89, 1.00) & (-0.89, -0.78, -0.33, -0.11) & (0.12, 0.37, 0.62, 0.75)
\end{bmatrix}
\]

The mean values of the elements of matrix \( V \) are shown in matrix \( M \):

\[
M = \begin{bmatrix}
A_1 & A_2 & A_3 \\
O_1 & 0.47 & -0.69 & 0.43 \\
O_2 & 0.57 & -0.72 & 0.69 \\
O_3 & 0.80 & -0.52 & 0.46
\end{bmatrix}
\]

The negative standard deviation of the elements of matrix \( V \) are shown in matrix \( \sigma^- \):

\[
\sigma^- = \begin{bmatrix}
A_1 & A_2 & A_3 \\
O_1 & 0.14 & 0.25 & 0.12 \\
O_2 & 0.19 & 0.26 & 0.29 \\
O_3 & 0.32 & 0.20 & 0.14
\end{bmatrix}
\]

The dominance and inferiority sets for each pair of options are:

- \( C_{12} = \{2\}; \ D_{12} = \{1, 3\}; C_{13} = \{\}; D_{13} = \{1, 2, 3\}; C_{23} = \{3\}; D_{23} = \{1, 2\} \)
- \( C_{21} = \{1, 3\}; D_{21} = \{2\}; C_{31} = \{1, 2, 3\}; D_{31} = \{\}; C_{32} = \{1, 2\}; D_{32} = \{3\} \)

The dominance matrix (\( C \)) and the inferiority matrix (\( D \)) are as follows:

\[
C = \begin{bmatrix}
O_1 & 0.39 & 0 \\
O_2 & 0.61 & -0.42 \\
O_3 & 1 & 0.58
\end{bmatrix} \quad D = \begin{bmatrix}
O_1 & -1 & 1 \\
O_2 & 0.12 & -1 \\
O_3 & 0 & 1
\end{bmatrix}
\]

Furthermore, we have:

\[ \bar{c} = 0.50 \; ; \; \bar{d} = 0.69 \]

So, the final dominance matrix would be:
As shown in matrix $F$, option $O_1$ is dominated by options $O_2$ and $O_3$, so this option is eliminated from further evaluation. For obtaining a more clear view about the dominance between $O_2$ and $O_3$, we use expressions 18 and 19. Thus, we have:

c_2 = 0.06; d_2 = -0.88

c_3 = 1.16; d_3 = -1

Since $c_3 \geq c_2$ and $d_3 < d_2$, we can conclude that option 2 is partially dominated by option 3.

5. CONCLUDING REMARKS

In some real-world situations, because of incomplete or unavailable information, the data are imprecise and expressed as fuzzy numbers. Electre methods are among the most popular MADM methods with a wide scope of application, like: classification of environmental impacts [12], facility layout problem [13], material selection [14], outsourcing (vendor selection) problem [15], etc. Despite the importance of Electre methods and the popularity of fuzzy environments, the fuzzy version of Electre methods was not published by the time that we submitted this paper. Hence, in this paper we developed Electre method for decision making in fuzzy environments. Our developed method is essentially based on Electrel with some small modifications. We suppose that the ratings of options and the weights of attributes are trapezoid fuzzy numbers. Since each triangle is an especial kind of trapezoid, our discussions can also be used for triangular fuzzy numbers.

\textbf{ABSTRACT}

This paper presents an efficient pulse width modulation (EPWM) drive method, which is used to implement the driving controller for TFT-LCD with high gray scale. To solve the time redundancy issues in the traditional pulse width modulation (TPWM) drive method, the proposed method divides the display panel into several sub-partitions and scans the sub-partitions alternately, and the gray data and vanishing signals are transmitted with separate wires in driving controllers. It’s theoretically proved that the drive efficiency can achieve 100% for any gray scale display systems with EPWM, and the implementation also shows that, comparing with the TPWM method, the minimum clock frequency in the TFT-LCD systems can greatly reduced with the proposed method.

\section{1. Introduction}

Because of their good overall performance, the thin film transistor liquid crystal displays (TFT-LCDs) have been becoming the mainstream products on the flat-panel display market. For TV applications, customers want not only the large screen size but also natural colours. So, larger screen size and higher definition have always been the goal manufacturers pursuing. However, the improvement of the screen size and definition is restricted by many factors, one important of which is the gray scale modulation method.

There are two voltage driving methods to realize the gray scale modulation of TFT-LCDs. Pulse amplitude modulation (PAM) method modulates the voltage amplitude to generate different gray scales. Pulse width modulation (PWM) method modulates the lighting time with a constant voltage through the pixels.\cite{1, 2, 3}

In order to improve the gray scale, the PAM needs high-accurate voltage amplitude scale while the PWM needs high scan frequency. However, it is difficult to realize the high-accurate voltage digital-to-analogue convector (DAC) and reach high system drive clock.\cite{4, 5}

In this paper, section II analyses the time redundancy issue existing in the Traditional Pulse Width Modulation (TPWM) drive method. Section III presents the Efficient Pulse Width Modulation (EPWM) drive method and proves that the drive efficiency of the EPWM drive method will be improved greatly. In section IV, the implementation of EPWM and the comparison between EPWM and other PWM drive methods are presented.

\section{2. Time Redundancy Issue of Traditional Pulse Width Modulation Method}

PWM (Pulse Width Modulation) drive method can be realized through several different forms. The time redundancy issues existing in the sub-frame modulation method, as an example, will be discussed.

The gray scale with the sub-frame modulation can be achieved by controlling the frame valid driving time according to the bit power of the pixel gray data. The gray value of a pixel is shown in the formula (1).
For a TFT-LCD with 8 levels gray scale, sub-frame modulation method divides a scan cycle into 8 time slices (or 8 sub frames). Then, the pixels can achieve different gray scales by turning on or turning off pixel voltage during the corresponding time slices shown in Table 1.

In Table 1, Nts represents the sequence number of the time slices. G represents the gray value and B represents the bit of the gray data. Bx represents the vanishing cycle.

From the table 1, we can find that the pixel voltage has the same state, turning on or turning off, at the 2nd and 3rd time slices. This means that the controller only needs to transmit a bit of gray data to the pixel at the 2nd time slice. The same situation occurs at the 4th, 5th, 6th and 7th time slices. The controller transmits available data, including gray data and vanishing signal, only at the 1st, 2nd, 4th and 8th time slices. We call these time slices available scan cycles, while other time slices are waiting time, which is called redundant time. Then the drive efficiency of sub-frame modulation is:

\[ E_d = \frac{N_d}{N_{all}} \times 100\% \]

Where \( N_d \) is the number of available scan cycles, and \( N_{all} \) is the number of total scan cycles.

It can be seen that the drive efficiency of TPWM is rather low. The minimum clock frequency will be higher and higher with the continuous increase of gray scale, which makes the display system hard to implement in practice.

3. Introduction of Efficient Pulse Width Modulation

To take full use of the redundant time, the TFT-LCD panel is divided into \( 2^n-1 \) sub-partitions [6, 7, 8] while any sub-partition can get the same target gray scale. The variable \( n \) is the number of bit of gray scale. One sub-partition is scanned in the redundant time of the other sub-partitions. By doing this, the drive efficiency will be improved greatly. Meanwhile, gray data is separated from vanishing signal in transmission process. Using this method, the scanning time of vanishing signal in TPWM method can be decreased. As a result, the clock frequency of the display system will be further reduced.

Our goal is to calculate the maximum sub-partition number (SN) and seek the proper drive sequence in order to maximize the scanning efficiency to attain about 100%. We will take the 4 levels gray scale and 8 levels gray scale as examples to illustrate how the controller scanning in different sub-partitions alternately.

3.1. Drive Sequence of 4 Levels Gray Scale

Our goal is to calculate the maximum sub-partition number (SN) and seek the proper drive sequence in order to maximize the scanning efficiency to attain about 100%. We will take the 4 levels gray scale and 8 levels gray scale as examples to illustrate how the controller scanning in different sub-partitions alternately.

For 4 levels gray scale display system, the TFT-LCD panel will be divided into two sub-partitions, labeled S1 and S2. Then they will be scanned alternately according to the order shown in Table 2.
Controller sends the available data in the following order: $B_1 (S_1) \rightarrow B_1 (S_2) \rightarrow B_0 (S_1) \rightarrow B_1 (S_2)$. A matter worthy of note is that the vanishing signal and gray data in 4<sup>th</sup> time slice will not conflict. This is because they are transmitted by two separate data lines. All of the five time slices are available scan cycle, so the drive efficiency is 100%.

### 3.2. Drive Sequence of 8 Levels Gray Scale

While the gray scale is 8 levels, the TFT-LCD panel will be divided into four sub-partitions, labeled $S_1$, $S_2$, $S_3$, and $S_4$. The drive sequence of 8 levels gray scale is shown in Table.3.

<table>

</tbody>
</table>

It can be seen clearly that the drive efficiency is still 100%, all of the thirteen time slices are available scan cycles. It will be discovered that the drive sequence of 8 levels gray scale can be derived from that of 4 levels gray scale when vanishing signals are not considered. This will be verified in the following section. It’s emphasized that additional vanishing signals are inserted to ensure the pixels voltage turning on for a valid time. For example, a vanishing signal is send to the sub-partition $S_3$ at the 7<sup>th</sup> time slice to ensure the bit power of $B_2$ maintaining four time slices. This is different from TPWM method, in which the vanishing signals are scanned lastly.

### 4. Theoretical Derivation of Efficient Pulse Width Modulation

We transform the drive sequence of 4 levels gray scale into matrix form, which is called drive matrix, shown in formula (3).

$$ M_4 = \begin{bmatrix} B_1 & & & \\ & B_1 & & \\ & & B_0 & & \\ & & & B_0 & \end{bmatrix}_{4 \times 2} $$

Similarly, the drive sequence of 8 levels gray scale can be expressed in matrix form in formula (4).
Where, $E_4$ equals to

$$
\begin{bmatrix}
B_2 \\
B_1 \\
B_0 \\
B_2
\end{bmatrix}
$$

which is called identity matrix. $0_{4\times2}$ is a zero matrix with 4 rows and 2 columns. All of the omitted elements in matrix $M_2$, $M_3$, $E_4$ are zero.

It can be discovered that the drive matrix $M_3$ can be derived from drive matrix $M_2$, and $M_2$, $M_3$ have some characteristics in common. Both matrix $M_2$ and $M_3$ have only one non-zero element every row, meaning only one available data is transmitted at every time slice. The number of non-zero elements in every column is 2 and 3 respectively, corresponding to the number of bit of gray scale.

A drive matrix must satisfy three conditions as follows.

1. The number of rows is $n \cdot 2^{n-1}$, and the number of columns is $2^{n-1}$. Where $n$ is an integer no less than 1, corresponding to the number of bit of gray scale.

2. There is only one non-zero element every row.

3. The number of non-zero elements in each column is $n$.

If a matrix $M_{n-1}$ is the drive matrix of $2^{n-1}$ levels gray scale, we can prove the matrix $M_n$ shown in formula (5) is the drive matrix of $2^n$ levels gray scale.

$$
M_n =
\begin{bmatrix}
\begin{array}{c@{}c@{}c}
E_{2^{n-1}} & 0 & \vdots \\
\vdots & \ddots & \vdots \\
0 & \ldots & M_{n-1}
\end{array}
\end{bmatrix}
$$

$M_{n-1}$ is the drive matrix of $2^{n-1}$ levels gray scale, which means there is only one non-zero element every row and there are $n-1$ non-zero elements every column. As $E$ is an identity matrix, it can be discovered easily that the matrix $M_n$ also meets the three conditions the drive matrix required. So, $M_n$ is the drive matrix of $2n$ levels gray scale.

The row number of matrix $M_n$ is $n \cdot 2^{n-1}$ and the number of non-zero elements in $M_n$ is $n \cdot 2^{n-1}$. If the drive sequence of display device is expressed as $M_n$, the controller will transmit $n \cdot 2^{n-1}$ available data at $n \cdot 2^{n-1}$ time slices. This implies the drive efficiency is 100%.
We can get the following conclusions through the analysis. For a n-bit gray scale display system, if it divides the whole TFT-LCD panel into $2^n - 1$ sub-partitions and employs the two-lines drive structure and the drive sequence expressed by $M_n$, the drive efficiency will attain 100%.

5. Implementation of Efficient Pulse Width Modulation

The implementation architecture of is shown in Figure.1.

In figure.1, the image data converter module decodes the image signal from micro processor unit (MPU) or digital visual interface (DVI), and writes the output RGB data to RAM. The controller of EPWM module is the key module in the display system. It not only controls the drive sequence of sub-partitions in accordance with drive matrix, but also generates the vanishing signals which determine the illumination time of the pixel together with gray data. The row driver IC and column driver IC generate gate and source driving voltage orderly, under the control of EPWM controller.

Clock frequency is one of the standards to measure the feasibility of a drive method. The TPWM drive method is impossible to realize, just because the clock frequency is too high to attain.

In the PWM drive method with no sub-partition division, the minimum clock frequency is required as:

$$f_{clk} = \text{refresh frequency} \times \text{row resolution} \times \text{column resolution} \times \text{gray scale levels}$$

(6)

In the PWM drive method with sub-partition division such as the Fractal Scanning Drive Method (FSDM)[7], the clock frequency is required as:

$$f_{clk} = \text{refresh frequency} \times \text{row resolution} \times S \times \text{pixels number per sub-partition}$$

(7)

Where, $S$ is the cycle number of a complete scan. It includes the scan of all gray data and vanishing signals of one pixel in each sub-partition.

In the practical interface between controller and display panel, the data width transmitted every clock is 8 bits or 16 bits. It’s assumed that the data width is 8 bits, then the actual clock frequency is

$$f_{act} = f_{clk} / 8$$

(8)

Then, for a 1024×768 dots RGB TFT-LCD, we can analogically calculate the drive efficiency and minimum clock of different gray scales with different drive methods, while the refresh rate is 60 Hz and data width is 8 bits. It is shown in table.4.

<table>
<thead>
<tr>
<th>Gray scale</th>
<th>Drive method</th>
<th>Drive efficiency</th>
<th>Minimum clock (MHz)</th>
</tr>
</thead>
<tbody>
<tr>
<td>64</td>
<td>TPWM</td>
<td>10.94%</td>
<td>377.49</td>
</tr>
<tr>
<td></td>
<td>FSDM</td>
<td>100%</td>
<td>41.29</td>
</tr>
</tbody>
</table>
From table 4, it can be seen TPWM is most inefficient and the minimum clock required is highest. When the gray scale is 1024 levels, the minimum clock frequency reaches 6057.49 MHz, which is impossible for the practical TFT-LCD display systems. Both of the FSDM and the proposed EPWM method can obtain 100% drive efficiency by making full use of redundant time, while the minimum clock frequency is far lower in comparison with that of TPWM. Since EPWM controller transmits the gray data and vanishing signals separately, the minimum clock frequency required is lower than that of the FSDM. For the 1024 levels gray scale display system, the minimum clock frequency with EPWM is only 58.99 MHz.

6. SUMMARY

The design calculation and system realization indicate that the proposed method can easily realize the high gray scale drive for TFT-LCD. With sub-partition division and two-line drive structure, the proposed method can obviously improve the drive efficiency and reduce the minimum clock. As a result, the realization difficulty of the high gray scale system is reduced.

\textbf{ABSTRACT}

Based on the mathematical model of the optimal scan architecture of grayscale imaging, this paper presents the design and logic implementation of a novel OLED greyscale controller with the fractal scan scheme to efficiently increase the scan utilization and imaging quality. Through the exploration of the sub-space code sequences and bit code sequences for different gray levels, we firstly complete the design and implementation of the parameterized fractal scanning IP core for various gray levels, which can be used to every flat panel display controller. And then we complete the design of a novel OLED grey scale controller that the fractal scanning IP core described with Verilog language is embedded in the FPGA hardware frame, which can efficiently increase the imaging gray levels and speed up frame frequency of display systems. Serial applications and tests indicate that it can obtain 100% scan utilization and a significant decrease of the system clock frequency (a multiple of 29 for 256 gray levels), comparing with traditional scan methods. With the proposed method there is no need to using high-speed IC circuits to realize the high articulation and resolution display of video images. Thus, the paper provides a new approach and an engineering way to solve one of the pressing problems of high resolution flat panel display technology.

1. INTRODUCTION

The Flat Panel Display (FPD), including TFT-LCD(Thin Film Transistor-Liquid Crystal Display), OLED(Organic Light Emitting Display), etc., that has been rapidly replacing bulky CRT based traditional displays plays an important role in exploring the progress of modern IT devices\cite{1,2}. As the high resolution flat panel display technology for large display size has been one of the key research fields, one of the bottlenecks which impede the technology development from current small display-size flat panel displays to high resolution large display-size ones are low grayscale scan utilization and efficiency. Xu et al. \cite{3, 4} proposed an innovative fractal scan structure which significantly increases scan efficiency. In their paper, they studied different scan schemes and constructed a mathematical model through the analysis of the fractal characteristics of space-time mapping topology. The theoretic model proved an optimal scan structure with maximum scan utilization.

Based on the aforementioned mathematical model\cite{5}, this paper presents the design and logic implementation of the fractal scan algorithm as a fractal scan intellectual property (IP) core for various gray levels, and then presents the system design and realization for OLED grayscale controller to testify the feasibility of using a fractal scanning IP core in the industrial applications, and the contribution for improving the parameters such as gray scale, frame frequency in FPD system. Compared with traditional scan methods, simulation and real application show 100% scan utilization and a significant decrease of system clock frequency (a multiple of 29 for 256 gray levels). Thus, the paper provides a new light to solving one of the pressing problems of high resolution FPD technology.

2. IP CORE WITH FRACTAL SCAN SCHEME FOR FPD

2.1. Fractal Topology for Optimal Scan

* Corresponding author: Tel.: (8621) 56331932; Fax: (8621) 56331632; E-mail: mhxu@shu.edu.cn
A key to the research of grayscale image scan algorithm is to convert the grayscale storage matrix into pixel lightening time. Hence, a space-time mapping topology for grayscale scan can be constructed at first. The grayscale matrix in space is then mapped to a grayscale scan space-time plane. Based on this mapping architecture, the optimal scan structure is explored. Since the paper is mainly focused on the logic implementation of the optimal scan algorithm and its application, interested readers can refer to the literature [3, 4, 5] for more details on different scan structures and methods.

Consider a scan line and rotate it by 90 degrees backward. Then the line and the time axis form a time-space plane, in which the horizontal axis represents the pixels and the vertical axis the grayscale scan time. For n-bit grayscale (n bits in the binary representation of the gray level), the entire time-space plane is partitioned vertically into Mn smaller planes (sub-spaces), each being of the same width. In each sub-space, there are n scan bits (scan for n times). For simplicity of discussion, denote Hk as the grayscale weight of the kth scan bit, E and T as the sum of weight of each scan bit, and the total scan time which is the sum of E and the blanking interval. As the plane is divided into 2n-1 sub-spaces, the optimal scan structure makes use of the interval between two scans of the same pixel (in the same column) to scan the pixels in other sub-spaces. The new scan scheme, according to the fractal characteristics of the structure, takes full advantage of the time interval and achieves 100% scan utilization.

Then rotate the time-space plane by 90 degrees anticlockwise for custom, namely the horizontal axis represents the grayscale scan time and the vertical axis the pixels. Figure 1 illustrates the zigzag fractal topology. The horizontal axis represents scan time, 40 scan time for every frame, and the vertical axis represents sub-spaces whose number is decided by the equation: Mn=8. The geometrical figures (■●◆▲) respectively denote the position and weight of the sub-space scanned currently. The rectangles beginning at black figures express the stable display time as soon as the corresponding sub-space received the scan data. The rectangle length is directly proportional to the weighted value. The white pentagrams show the last blanking disposal for every frame.

Each of the eight sub-spaces is scanned 5 times in total at the time (horizontal) axis. The scan distance for the first four scans is among 1 (H1=1), 3 (H2=3), 8 (H3=8) and 20 (H4=20), which corresponds to the grayscale weight. At each time unit, only one sub-space is scanned. The last eight scans (t32 to t39) deal with blanking.

Connecting every geometrical figure in term of time, the “Z” pattern emerges as the self-similar fractal topology.

2.2. Architecture of Fractal IP Core

The fractal scan module is shown in Figure 2. Each signal is defined in Table 1. The function of the module is to implement the fractal algorithm in digital logic. In the figure, NB is the bit width of the bit code and NS the bit width of the sub-space code. NB is determined by the gray levels and NS by the scan scheme. Since there are 2n-1 sub-spaces for n-bit grayscale, and NS = n-1. At the positive edge of the clock when GetNext is asserted (GetNext = 1), the module outputs current bit code Bit[NB-1:0], sub-space code Segment [NS-1:0], and the Hidden signal to control row/column addresses and gray value.
